In a double-blind trial 0.1% betamethasone 17-valerate ointment (Betnovate) has been compared with 0.25% fluocortolone and 0.25% fluocortolone caproate compound ointment (Ultralanum Plain) in the treatment of eczema and psoriasis, with and without polyethylene occlusion. The betamethasone 17-valerate ointment was significantly better than the fluocortolone ointment in patients with eczema treated without occlusion, and in psoriasis, with or without occlusion. No significant difference was demonstrated in cases of eczema treated with the ointments and occluded with polyethylene.

Medical Memoranda

Unusual Cause of Charcot Joints in Early Adolescence (Riley-Day Syndrome)

Brit. med. J., 1967, 4, 277-278

Familial dysautonomia, a disease almost completely confined to Ashkenazic Jews, was first described by Riley *et al.* (1949). Recently interest has been renewed in searches for the basic defect of this puzzling clinical picture, which as yet remains unknown (Dancis and Smith, 1966; Riley and Moore, 1966). It is known to be transmitted as an autosomal recessive trait, which suggests a single enzyme defect as a possible cause (McKusick *et al.*, 1967).

The characteristic manifestations are not confined to the autonomic nervous system, as the name might imply. Common clinical features are defective lacrimation, which, coupled with corneal hypalgesia, may lead to ulceration of the cornea; relative insensitivity to pain (some children have had fractures set without anaesthesia); defective taste sensation coupled with absence of the fungiform papillae of the tongue (the latter being probably pathognomonic); orthostatic hypotension and paroxysmal hypertension; bouts of unexplained pyrexia; kyphoscoliosis; incoordination and dysarthria; areflexia; emotional lability; defective swallowing; and characteristic responses to certain drugs (Dancis and Smith, 1966). Though the condition is often manifest in the first days of life, the late effects in adolescence may bring the patient to doctors in various specialties. While diminution in pain sensitivity is a well-established phenomenon in this disease, neuropathic joints have not hitherto been described.

CASE HISTORY

The patient, a girl aged 12 years at the time of study, first developed swelling of the left knee at the age of 9 years. She was

born of Jewish parentage (both of Eastern European origin but without known consanguinity), the pregnancy and delivery being uneventful. There is one normal older sib. Feeding difficulties occurred from birth and recurrent fever and respiratory infection were common in the early years of life. The diagnosis of familial dysautonomia was confirmed at 12 months. A moderate degree of incoordination, diminished sensitivity to painful stimuli, and corneal ulceration were all noted.

At the age of 9 years she quite suddenly developed painless swelling of the left knee (due to effusion), which was attributed to trauma, though there was no clear history of this. The knee seemed to be "dislocated," and in subsequent months "gave way on her" repeatedly. The swelling never completely subsided and the knee has remained disorganized and unstable but at all times pain-free. At age 11 years, two years after the initial onset, the right knee became swollen and deformed. Bilateral brace supports were required. A fairly severe degree of kyphoscoliosis had also developed over this period.

Examination of the knees showed bilateral swelling and deformity (Fig. 1) with knock-knee stance (and unsteady gait). There was considerable effusion into the right knee and some degree of lateral mobility with marked instability of the joint and audible crepitus. The left knee was somewhat less swollen but was grossly disorganized,

FIG. 1.—The knees at age 12.

FIG. 2.—X-ray films of right knee at age 11.

FIG. 3

FIG. 4

Figs. 3 and 4.—X-ray films of right knee at age 12.

with hypertrophic changes on the medial aspect of the joint and with shift of the patella laterally.

Neurological examination revealed hypotonia and absent deep tendon reflexes. Cerebellar function appeared intact. Light touch and position sense were normal, but vibration sense was somewhat diminished and pain sensation greatly reduced. Temperature sensation also appeared to be diminished.

Figs. 2-4 show the right knee, the radiological changes in the left knee being similar but less severe. At age 11, soon after the initial symptoms in the right knee, there was considerable destructive change involving principally the lateral aspect of the epiphysis (Fig. 2). A year later (Figs. 3 and 4) soft-tissue calcification and ossification were visible. There was subluxation and irregularity of the femoral condyles. The ossification was compatible with Pelligrini-Stieda fracture, indicating recurrent trauma to the joint.

COMMENT

In attempting near complete ascertainment of cases in the North American continent we (McKusick *et al.*, 1967) have obtained first-hand information on 164 families (200 patients). Among the 60 children examined in detail we have found two further young adults with similar joints—one with a painless, acutely swollen, disorganized knee joint and the other with a painless arthropathy of the shoulder.

Charcot joints occurring before closure of the epiphyses are rather uncommon and present different radiographic findings

from the more usual adult picture. Though most reports of familial dysautonomia have appeared in the American literature, there are three reports in British journals (McKendrick, 1958; Hutchison and Hamilton, 1962; Keith, 1965) and one in Australia (Burke, 1966), and other cases in the United Kingdom are known.

My thanks are due to Professor Victor A. McKusick for his kind encouragement and permission to publish this case.

Spinal Subarachnoid Haemorrhage in Patient with Coarctation of Aorta

Brit. med. J., 1967, 4, 278-279

Patients with coarctation of the aorta are liable to develop cerebrovascular complications (Woltman and Shelden, 1927; Tyler and Clark, 1958). Intracranial haemorrhage with or without a demonstrable aneurysm occurs in some 12% of untreated cases (Reifenstein *et al.*, 1947). Spinal complications are much rarer (Weenink and Smilde, 1964). They are believed to be due to ischaemia resulting from reduced blood flow to the lower portion of the cord, and from vascular abnormalities associated with the collateral circulation. This paper describes the occurrence of paraplegia after spinal subarachnoid haemorrhage in a patient with coarctation.

CASE REPORT

A 44-year-old woman was admitted to Sydney Hospital in May 1964 with confusion, severe pain between the shoulder blades, and loss of power in the legs.

At the age of 7 she had been known to have a heart murmur, and at 12 had been diagnosed as having "rheumatic carditis," the illness consisting of slight fever, chest pain, occasional involuntary writhing movements, and sore joints. At 14 she had a systolic blood pressure of 180 mm. Hg, for which she was not treated. During her second pregnancy, at the age of 25, she had an episode of loss of consciousness while in hospital for an antepartum haemorrhage. On regaining consciousness she had no neck stiffness or headache and no residual neurological symptoms. She was told that she had had a "cerebral haemorrhage," and caesarean section was carried out with delivery of a normal infant.

At the age of 42 a chest x-ray film taken during a mass survey showed rib notching and an enlarged heart. Clinical examination revealed a blood pressure of 220/90, with femoral pulses greatly diminished in intensity and delayed in comparison with the radial pulses. The second heart sound was increased in intensity, and

a soft systolic murmur was heard at the apex, left sternal border, and between the scapulae. Conservative treatment with guanethidine 50 mg., rauwolfia 4 mg., and bendrofluazide 5 mg. daily was decided on, and she remained well until admission.

On the day of admission she was on the toilet when she felt a strange sensation in the back "as if something were shooting up her spine," and she was unable to get up. She was carried to her bed, and there lost consciousness for several minutes. On arrival at hospital one hour later she was confused and complained of severe pain between the shoulder blades, frontal headache, and inability to move her legs, but had no neck stiffness. On examination the blood pressure was 220/90, with other findings in the cardiovascular system essentially unchanged. There were coarse crepitations at the base of both lungs. Cranial nerves and fundi were normal. Motor power and pain and temperature sensation were lost below the level of T8. Vibration, light touch, and position sense were unimpaired. Knee and ankle jerks were absent bilaterally, as were the plantar reflexes. There was tenderness over T5 and 6. Spine and neck rigidity developed a few hours after admission.

The C.S.F. was grossly blood-stained, with a pressure of 160 mm. of water, a protein content of 154 mg./100 ml., and a glucose content of 35 mg./100 ml. The blood urea nitrogen was 15 mg./100 ml., and the haemoglobin concentration 16.6 g./100 ml. A blood film showed neutrophilia with a white cell count of 26,000/cu. mm. Plain x-ray examination of the abdomen showed no evidence of dissection. Apart from some pulmonary oedema the chest x-ray picture was unchanged. A left carotid angiogram was inconclusive, due to spasm of the anterior cerebral artery, and a right carotid angiogram was normal. A myelogram showed the dye to flow freely to the base of the skull, but in the lower cervical, upper thoracic, and mid-thoracic regions there were numerous filling defects suggestive of grossly dilated vascular structures. The lumbar puncture was repeated three days after admission, the Queckenstedt test showing no transmission of impulses. The C.S.F. was blood-stained with xanthochromia.

Leg power and sensation improved over the next few days, and full voluntary control of the bladder was present. Two weeks after admission the patient had an episode of loss of consciousness lasting five minutes, with masseter spasms and incontinence of urine and faeces. When she regained consciousness she complained of severe back pain; her physical signs were essentially unchanged. The next day a laminectomy performed at levels of T7 to T10 showed

blood-clot filling the subarachnoid space with no abnormality of the cord. One abnormal dilated vessel was found and tied off, and there was no further active haemorrhage.

Postoperatively the pain in the back disappeared, but she could move only her toes and regained no other active movement in the legs. When last seen in 1966 her blood pressure was over 300/120, and there were signs of inadequate blood supply to the legs. She was otherwise well, using a wheel-chair for ambulation.

COMMENT

The aneurysmal dilatations of collateral vessels in coarctation of the aorta are well documented in the literature (Boyd and Werblow, 1937; Cleland *et al.*, 1956). Histologically the walls of these dilated vessels are deficient in muscle and elastic tissue, and in some places they are composed solely of intima and adventitia (Cleland *et al.*, 1956). These changes may affect the spinal arteries as well as other collaterals. Wyburn-Mason (1943) recorded a total of seven cases in which enlarged tortuous spinal arteries with or without local aneurysm formation were found in cases of coarctation. Weenink and Smilde (1964) found a dilated anterior spinal artery at necropsy in a patient who presented with paraplegia of sudden onset.

The combination of spinal subarachnoid haemorrhage and coarctation of the aorta has, to my knowledge, been reported only once before (Wyburn-Mason, 1943). This patient had temporary weakness of one leg after the haemorrhage. Henson and Croft (1956), in their review of spinal subarachnoid haemorrhage, found permanent paraplegia directly due to the haemorrhage to be a rare occurrence.

Paraplegia with loss of pain and temperature and retention of touch and joint position sense is characteristic of the anterior spinal artery syndrome (Peterman *et al.*, 1958; Henneaux, 1960). The mechanism of its production in the above case must remain in doubt. The anterior spinal artery may have been compressed by clot. There may have been arterial spasm (Paulson, 1963), or, most likely, a portion of the cord previously supplied by the ruptured vessel became ischaemic.

My thanks are due to Associate Professor Solomon Posen and Mr. C. R. Letham for allowing me to see the patient and for their continuing interest.

True Heartburn

Brit. med. J., 1967, **4**, 279-280

Heartburn, while sounding like a pathological description, is a descriptive term common in dyspeptic symptomatology—a symptom that most people experience and one that is not normally regarded with any great apprehension, nor does it carry a connotation of cardiac pathology. However, exceptions occur and the following case is one of them.

CASE REPORT

The patient, a bachelor aged 45 living with his mother, for many years had been a seaman, but during the previous two years had been working as a coffee roaster. On 7 January 1967 while sitting at home with his mother and feeling depressed as a result of delusions of persecution, he placed a poker in the fire and watched it heating until it was red. When he thought that the maximum heat had been generated on the tip of the poker he placed it over his heart and pushed hard. With little or no sensation of pain he observed that the poker passed quite easily into his chest; he felt faint and fell on the floor. His mother summoned the neighbours for assistance, and, as it was seen that, though pale, he was still alive, the ambulance was summoned. He was admitted to the Western Infirmary in the early hours of 8 January.

Observation from a distance showed that the handle of the poker was projecting from the fourth left interspace, about 8 cm. from the midline (Fig. 1). Oscillation of the poker indicated that the heart was beating and the pulse rate was 120 per minute. His blood pressure was 80/50 mm. Hg and he was pale, perspiring, but not in any respiratory embarrassment. On closer observation it was seen that there was a ring of charring around the entrance wound, and that there was little or no haemorrhage. A lateral x-ray film taken with a portable machine confirmed what was already obvious, that the larger portion of the poker was in the left thoracic cavity.

Intravenous infusion was immediately begun and plasma administered, which produced a rise in systolic pressure to 100 mm. Hg. At this point it seemed prudent to explore the left thorax to determine the exact nature of the tissue damage. The chest was opened by an anterolateral incision through the fifth interspace. The lung was found to be collapsed and there was 200-300 ml. of blood in the thoracic cavity.

Fig. 1.—Entry wound in fourth left interspace.

Fig. 2 shows how the poker had passed through the pericardial cavity, the tip of the poker resting about 2 cm. from the posterior thoracic wall. There was no evidence of injury to the lung, but both entrance and exit wounds in the pericardium showed evidence of charring, and when the bridge of pericardium was divided it was seen that an area of the left ventricle, 2 by 4 cm., was whitened and clearly had been burnt as the hot poker passed over it. There was no active bleeding, and the poker was withdrawn without causing any further damage. Cardiac action seemed normal, and, as the patient's blood pressure had risen to normal levels after the transfusion of 2 pints (1,140 ml.) of blood, it was decided that no further action should be taken about the burning of the myocardium. As

a result of loss of tissue, the pericardium could not be sutured. A drain was inserted into the thoracic cavity and the thoracotomy wound was closed.

The first two days of his convalescence were marked by persistent hypotension, but tissue perfusion always seemed adequate and urinary secretion was established normally. There was some diminished air entry on the left side, and some evidence of collapse of the left lung. After these two days his convalescence progressed fairly satisfactorily. The main surgical complication of the con-

FIG. 2.—Position of poker in left hemithorax.

valescent period was a continued discharge from the front end of the thoracotomy wound, which was due to the establishment of an abscess cavity involving pericardial and thoracic cavities. With drainage this gradually closed, and, though one sinogram showed evidence of a bronchopleural fistula, the cavity closed without further complication.

The electrocardiographic changes were particularly interesting. The first tracings after operation were consistent with a recent anterior myocardial infarction (Fig. 3). Widespread ST elevation was consistent with some degree of pericarditis. The most recent tracings (2 June) showed that ST elevation in anterolateral leads persisted. The absence of Q waves seemed to exclude the possibility of a ventricular aneurysm and screening of the chest also showed no evidence of an aneurysm. His clinical condition was excellent: he had no residual cardiac or respiratory symptoms; the anterior end of his wound had healed; and he had returned to his former occupation. His psychiatric state was investigated and the opinion was that he was suffering from a paranoid psychosis, though his suicidal act had apparently produced a remission in his mental symptoms. During his stay in the ward he was a model patient, and a casual observer would have found no abnormality in his mental attitude. He continued to attend as an outpatient for further psychiatric supervision. He had lost his delusions and acquired a myocardial scar.

COMMENT

There appear to be no references to similar cases in the literature. Rivkin (1963) and Tedeschi and White (1954) both reported on burning injuries to canine hearts in the course of studies designed to find out the damage caused to cardiac musculature by electric defibrillation. The lesions produced are similar to those that could be produced by myocardial infarction, but there seems to be no study determining the long-term behaviour of burnt areas of myocardium. In the present case the assumption is that the patient will behave as one who has had an anterior myocardial infarction. The prog-

nosis should be good, as there is no occlusion of the main coronary vessels and it is likely that the anastomotic circulation is good. E.C.G. tracings do not suggest that the area of necrosis penetrated the full thickness of the myocardium, so it is not likely that he will develop an aneurysm. In a discussion with the patient it was not possible to find out why he chose this particular method of committing suicide except that the

FIG. 3.—Electrocardiographic tracings; left, a day after injury (January 1967); right, six months later (June 1967).

poker was handy; the actual idea of suicide did not occur until the poker was already heated and glowing red.

This case is recorded as the first reported true case of acute heartburn, and also as an example of an avoidable cause of myocardial infarction.

My thanks are due to Dr. Ian Short and Dr. Gerald Timbury for their advice on the medical and psychiatric care of this case, and to the Department of Medical Illustration, Western Infirmary, for the illustrations.

Current Practice

DISEASE OF THE DIGESTIVE SYSTEM

Duodenal Ulcer—I

IAIN E. GILLESPIE,* M.D., F.R.C.S.

It is the purpose of this paper to discuss duodenal ulcer under three headings: diagnosis, medical management, and indications for elective operation. The treatment of emergency complications such as perforation and haemorrhage will not be considered.

Diagnosis

Duodenal ulcer continues to be a common disorder in Britain. It still shows a predominance in males, though there is a suggestion that the difference in incidence between the two sexes may not be as great as it was 20 years ago. Reliable data on the overall incidence of peptic ulceration is understandably difficult to acquire in view of the very variable severity and natural course of the disease. If the incidence of perforation is one factor capable of fairly precise measurement, there is evidence¹ that at least in one part of the country there has been a real decrease in the number of such complications in the last ten years. Although several interpretations of this finding are possible, it may be that it reflects a recent change in the incidence of duodenal ulcer, just as there is evidence that the pattern of gastric ulcer, at least in Australia, may also be changing.²

The diagnosis of duodenal ulcer is usually strongly suspected from the clinical history alone. The chief and often sole complaint is of epigastric or right hypochondriac pain or discomfort most frequently experienced when the patient is hungry, and by the time he seeks medical advice he has generally noted that eating a meal affords substantial relief for an hour or two. There may also be recurrence of the upper abdominal pain during the night, and if this causes interruption of sleep the patient often has noticed that drinking a glass of milk or taking a small snack will let him return to his sleep. Vomiting is not as common an occurrence in patients with duodenal ulcer as it is with gastric ulcer, but in a minority of duodenal ulcer patients even without pyloric stenosis some vomiting does from time to time occur. Usually this is of partly digested food or clear gastric juice, and the act of vomiting often brings relief of abdominal discomfort. A few patients may deliberately induce vomiting to obtain such relief. Repeated attacks of copious vomiting, particularly of retained gastric contents, do of course suggest the occurrence of pyloric stenosis.

By the time the patient seeks medical help he has usually experienced several episodes of his pain or discomfort with remissions of variable length intervening. Since a large variety of antacid and other "indigestion" preparations are widely advertised, and readily available, most patients will have tried one or several of such preparations. Most will have experienced at least partial relief from this self-selected medication, and a good proportion will claim that a dose of bicarbonate of soda is as good as anything to ease the pain.

Radiation of the pain through to the back usually occurs only in the most severe relapses of ulcer pain, and this feature is

generally taken to indicate a posterior ulcer irritating or penetrating into the retroperitoneal tissues.

There does not seem to be any particular group of food substances which are regularly blamed for the onset of ulcer dyspepsia. Many patients complain, however, that spicy or greasy foods do bring on their symptoms, though intolerance of such foods seems to be a non-specific feature of most disorders of the upper digestive tract. An individual patient with a duodenal ulcer may relate the somewhat abrupt onset of his symptoms with the ingestion of a particular food substance and therefore believe that it was responsible for the symptoms. However, the variety of foods blamed in this way is so large that no set pattern emerges.

Barium-meal examination will confirm the diagnosis in the majority of cases, and it is reasonable to expect a diagnostic accuracy of over 90%. The largest ulcers will usually be clearly shown directly, and for the remainder the indirect signs of deformity of the duodenal cap, abnormalities of the mucosal pattern, or difficulty in satisfactory filling of the duodenal cap will give the diagnostic indications. It is not an uncommon experience for those clinicians and radiologists who regularly jointly review ulcer patients to find quite gross disparity between the x-ray findings and the severity of the clinical history at the time of the examination. Quite minimal deformity of the duodenal cap may be seen in a patient having severe pain almost incapable of relief by medical measures, while by contrast a large ulcer crater with gross scarring of the duodenal cap is found in a patient having minimal dyspepsia. Because of this variable relation between clinical history and radiological findings, when a patient has convincing symptoms of a duodenal ulcer but an apparently normal barium meal it is reasonable to repeat the examination after an interval of a few months should the symptoms persist. Even with repeated expert radiological examination a few duodenal ulcers may escape x-ray detection and come to light only at a subsequent laparotomy. This is unusual, and is more likely when the ulcer is abnormally situated.

Who Do the Barium Meal?

It might be argued that if the symptoms are quite typical and clear-cut there is no necessity to perform the barium meal. This argument is not valid. It is important to have the x-ray results in all suspect cases for several reasons. Firstly, it is virtually impossible on symptomatology alone to differentiate with any confidence between duodenal and gastric ulcer, and since there are some important differences in the management of the two types of disorder it is essential to know the location of the ulcer. Secondly, the concurrent presence of both duodenal and gastric ulcers is being recognized increasingly frequently, and it is important to detect this. Thirdly, other abnormalities of the upper alimentary tract such as hiatus hernia, congenital abnormalities, or diverticula may be present and have a bearing on treatment.

* Senior Lecturer in Surgery, University of Glasgow.

In most patients the diagnosis is adequately established by barium-meal examination, but a number of further diagnostic aids may be valuable in special circumstances.

Gastroscopy.—Inspection of the gastric lumen by the flexible fibroscope or the direct-viewing gastro-camera is indicated in patients with a strong dyspeptic history and a normal barium-meal examination. The gastroscopic examination may reveal a small undetected gastric ulcer or other gastric lesions but will of course not normally permit direct inspection of the duodenum itself.

Acid Secretion Measurements.—The diagnostic application of these tests is quite limited. Assessment of the maximal acid response to either histamine³ or more recently the synthetic gastrin-like pentapeptide pentagastrin⁴ has replaced other tests of acid secretion. Though the maximal acid response of duodenal ulcer patients is twice that of normal controls there is a very large range of individual values in each group and considerable overlap between the two groups. Thus a high value for the maximal acid response in an individual patient will not clearly establish the diagnosis of duodenal ulcer, but will only make the diagnosis more likely. In return for the high order of close supervision, thoroughness, and time-consuming care which must be expended to obtain reasonably accurate secretory measurements the diagnostic usefulness of these tests is disappointingly small.

Where the clinical history may raise the suspicion of the very rare Zollinger-Ellison syndrome (unusually severe ulcer dyspepsia, multiple ulcers on radiological examination, and/or severe watery diarrhoea), comparison of the unstimulated gastric acid secretion with that obtained after maximal stimulation with histamine or pentagastrin may add considerable support to the diagnosis. In this condition it is characteristic, though not invariable, to find a very large output of acid in the unstimulated phase as a result of the continuously large production of the gastrin-like secretagogue from the pancreatic tumour, and the additional administration of a "maximal" dose of histamine or pentagastrin does not bring about much further increase in the gastric acid secretion.

There has been much interest in the relationship between peptic ulceration and blood group distribution. The present position, recently reviewed by Langman,⁵ may be briefly summarized as follows. Both duodenal and gastric ulcers are more likely to occur in persons belonging to blood group O, particularly if they are incapable of secreting the blood group substances in their mucus secretion. The increased risk of these group O non-secretors, though statistically significant, is relatively slight, and a knowledge of the blood group and secretor status of an individual patient with duodenal ulcer does not at present help in establishing the diagnosis or in planning the clinical management.

Medical Management

Most duodenal ulcer patients are treated in the first instance by conservative measures: advice regarding diet, drugs for symptomatic relief—such as alkalis, anticholinergic drugs, and sedatives, and some advice regarding the general pattern of daily life, work routine, and social activities.

Diet

Traditionally patients have been advised to restrict their dietary intake to "bland" constituents with a predominance of milk, milk-containing foods, and carbohydrates. In the past quite detailed restrictions have been advocated, such as milk and fish for prolonged periods. There is no good evidence that such strict limitation of diet is of any real value in achieving symptomatic relief or in preventing further relapses. Detailed advice should not be given on foods to be preferred or avoided. Many patients find it difficult if not impossible to stick to a grossly limited diet during a normal day. The patient should

be told simply to avoid any particular items which have regularly caused a bout of dyspepsia. Foods which are highly seasoned should probably be avoided, as many spices are known to have a local irritant action on the gastric mucosa, unless the patient is inordinately fond of them and has found that he can eat them without any discomfort.

Since nearly every duodenal ulcer patient finds that a drink of milk will give prompt relief of the ulcer pain, an increased intake of milk or milk-containing drinks spaced frequently throughout the day is often recommended. However, there is no real evidence that milk is better than other substances in neutralizing gastric acid or in any other way. The patient with a duodenal ulcer may be advised to take extra milk if he likes it, with and between meals, but there seems no justification in insisting that those patients who strongly dislike milk should take it.

Timing of Meals

The timing of meals is probably much more important than the actual food. Lennard-Jones and Babouris⁶ have shown that there is much less fluctuation in intragastric pH when a diet of the patient's own selection is fed at two-hourly intervals as compared with four-hourly. Translated into practical terms this means that the patient should be urged to have a mid-morning and mid-afternoon snack in addition to the three main meals, and that he should also have something to eat in the middle of the evening and last thing at night before retiring to bed. Sometimes the patient's occupation makes this regimen difficult, but it is generally possible to persuade him to carry some packaged food with him and to take this at the appropriate times.

For how long should such a diet pattern be followed? There is unfortunately no clear-cut guide on this question, but it is probably unnecessary to prolong it beyond a few weeks after complete remission has occurred. A gradual return could then be made to normal spacing. The patient should be told that it is unwise for him to miss a meal or go for much longer than three to four hours without something to eat.

This advice is likely to lead to an increase in weight, and on occasions to gross obesity. Fortunately patients with duodenal ulcer on average tend to be a bit underweight, and the weight gained as a result of the dietary measures may not always pose too much of a problem.

What advice should be given about the taking of alcohol? Alcohol is known to stimulate the gastric secretion of acid, and it is also known that excessive quantities of ingested alcohol can cause a diffuse gastritis. It is doubtful whether it is necessary to forbid the taking of alcohol altogether, but patients should avoid spirits and should not take any alcohol when fasting.

Drugs

Alkalis.—Most patients find that one or other of the very numerous alkaline preparations available will give effective symptomatic relief. Perhaps the most popular remedies contain aluminium hydroxide, phosphate, silicate, or glycinate, magnesium trisilicate, hydroxide, or carbonate, calcium carbonate, or bismuth aluminate. It is common clinical experience that though some preparations enjoy a fairly wide popularity among duodenal ulcer patients there is considerable variation in the apparent effectiveness of different drugs and mixtures from one individual to another. Again it is often found that whereas one alkaline preparation will regularly afford relief for months or years it may eventually lose in usefulness and the patient will switch to another preparation which apparently then proves superior. This in turn through time may eventually be superseded by yet another antacid, and yet all three

preparations might have virtually the same capacity to neutralize acids. It is often surprising how rapid and prolonged is the relief obtained from a relatively small dose of an alkaline preparation, a dose which would be able to neutralize only a very small quantity of acid. It seems that the symptomatic relief afforded by alkalis is not solely explained by their acid-neutralizing properties, since the quantities theoretically required to keep the stomach contents at an alkaline pH for prolonged periods throughout the day are many times the doses normally taken by duodenal ulcer patients.

Since the aim of giving antacid preparations is simply to give temporary symptomatic relief and not to secure continuous acid neutralization, the alkali should be taken by the patient only as and when required for relief of pain. There seems no virtue in taking doses regularly throughout the day at set times or in relation to meals, and there is no justification for giving alkalis during a period of remission in the hope that they will minimize the chance of recurrence of symptoms.

To some extent side-effects will dictate the choice of an antacid preparation. Those containing magnesium tend to cause mild diarrhoea, whereas aluminium hydroxide may have the opposite effect. If taken in very large dosage calcium carbonate and bicarbonate and sodium bicarbonate may cause alkalosis.

Anticholinergic Drugs.—Though not so popular as alkalis anticholinergic drugs are also widely used in the symptomatic treatment of ulcer dyspepsia. If given in adequate dosage it can be shown that such drugs will both reduce gastric acid and pepsin secretion and also diminish gastric motility. For this last reason the anticholinergic drugs have often been referred to as "antispasmodics," there being a belief that muscular spasms may cause or contribute to duodenal ulcer pain. Among the most commonly prescribed anticholinergic agents are atropine and hyoscine and their derivatives, poldine, propanthelene, dicyclomine, and glycopyrrolate. It is probably fair to say that such agents are not as commonly effective as the antacid preparations, but a proportion of patients do find anticholinergic drugs completely effective in obtaining prompt relief. This variation in the usefulness of different symptomatic remedies may reflect individual variation in the mechanism of ulcer pain.

There is evidence⁸ that anticholinergic drugs should be given in maximal tolerable dose in order to obtain significant relief of symptoms. Dryness of the mouth, blurring of vision, and occasionally difficulty in emptying the bladder may occur if excessive dosage is taken, and it may not always be possible to obtain satisfactory relief of the dyspeptic symptoms with a dose which does not cause these unpleasant, and at times risky, side-effects.

Sedatives.—The idea behind giving sedation to patients with duodenal ulcer arose from the concept that patients with this disorder were unduly prone to worry excessively, to be over-active, agitated, and introspective, and that this pattern was in some way causally related to their duodenal ulcer. It was also argued that, since a period of rest in bed would virtually always result in the disappearance of even the most severe ulcer symptoms, sedation might go at least some way towards achieving a more tranquil background for the patient and so encourage the healing of his ulcer. Small doses of sedatives, notably phenobarbitone, are commonly added to proprietary antacid preparations. There is, however, no good evidence that sedatives improve the chances of obtaining satisfactory remission or prevent further symptoms. However, such drugs may be useful in a selected minority of patients displaying marked nervous excitability.

Over the years the effect of oestrogens has been noted in the duodenal ulcer, following the reasoning that the lower incidence of duodenal ulcer in females might be due to the sex hormone might protect against the disease. Truelove⁹ in a carefully controlled trial of 0.5 mg. b.d. exerted a

beneficial effect on the symptom course and on healing rates in men with duodenal ulcers. Unfortunately, as might be expected, a relatively high incidence of feminizing side-effects weighed heavily against widespread use of such treatment. A few further recent attempts have been made to evaluate oestrogen preparations with less feminizing side-effects, but results have been inconclusive. While further evaluation is awaited with interest, there seems no indication at present for oestrogen therapy in the routine management of duodenal ulcer patients.

Carbenoxolone.—Carbenoxolone is an anti-inflammatory agent isolated from liquorice extract, and a variety of similar preparations have been used for many years in the medical management of peptic ulceration. While there is some evidence that carbenoxolone may facilitate the healing of gastric ulcer in ambulant patients, there is at present no indication that it exerts a favourable influence in duodenal ulcer. Most liquorice preparations, including carbenoxolone, cause retention of water and sodium when given in moderate or high doses, a property incidentally shared by oestrogens. It may well be that this fluid-retaining property is an essential aspect to the therapeutic value of these drugs.

Anti-pepsin Agents.—A number of agents have been found to inhibit the proteolytic enzyme action of pepsin under laboratory conditions. However, to date none has been shown to perform this role satisfactorily *in vivo*, and such a therapeutic approach is not promising.

General Aspects

Rest.—It is common experience that peptic ulcer symptoms rapidly remit when the patient is put to bed. Whether the physical inactivity or the isolation from "stresses" of occupational, social, domestic, and other responsibilities is the more important factor is uncertain. Whereas it is not always practical or indeed possible for a patient in relapse of duodenal ulcer symptoms to take to bed, it is on occasion worthwhile advice to a patient who is having increasingly severe pain which proves intractable to other measures. The response of symptoms to a short period of bed rest is also sometimes used to determine whether the pain is genuinely due to duodenal ulcer or some other lesion. If the pain does not subside when the patient is confined to bed this is usually taken as an indication that the pain is not due to peptic ulceration. While this is not an absolute rule it is often a useful guide.

Psychological Factors.—The importance of psychological factors in the aetiology and natural course of duodenal ulcer remains uncertain and controversial. Opinions vary from the extremes of the belief that virtually all peptic ulcers are the expression of emotive disorder and conflict, to the view that any expressions of reaction or behaviour abnormalities are the consequences of the peptic ulcer state. The compromise view is that psychic disturbance is of importance in a proportion of patients only. Many clinicians can readily recall patients whose symptoms regularly flared up on exposure to a particular emotional problem and promptly settled once more on the problem being overcome. Where such factors can be clearly recognized it may be possible to help the patient avoid exposure to the precipitating factors by some simple commonsense advice, or to modify the patient's reaction to the particular circumstance by enlisting the aid of the professional psychotherapist. In many instances, however, though there may be aggravating work or social factors, it may be quite impractical to alter the situation.

Smoking.—There are many good reasons for advising a cigarette smoker to give up the habit, and these apply no less in the duodenal ulcer patient than in any others. Doll, Jones, and Pygott¹⁰ showed in 1958 that stopping smoking accelerated the healing of gastric ulcer. There is still a surprising lack

of information on the effects of cigarette smoking on the course of duodenal ulcer. At present, therefore, any advice to stop smoking is based on general grounds.

Gastric Freezing.—The initial enthusiasm for gastric mucosal freezing has not been sustained. Clinical experience with this technique has been reviewed by Forrest,¹¹ who concludes that there is no place for this method of treatment in the management of chronic duodenal ulcer at the present day.

(This article will be concluded next week with an account of the surgical management of duodenal ulcer together with a list of references.)

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Analgesics and Monoamine-oxidase Inhibitors

Q.—What untoward reactions may occur when analgesic drugs are given to patients who have been taking a monoamine-oxidase inhibitor drug? How may severe pain of acute onset be treated in such patients?

A.—There have been a number of reports of untoward reactions when analgesics have been given to patients who were receiving monoamine-oxidase inhibitors such as iproniazid, phenelzine, nialamide, pargyline, and tranlylcypromine.¹⁻³ In most of the reported cases the analgesic concerned has been pethidine.

The more alarming type of reaction occurs within minutes of the administration of pethidine. The patient becomes restless, even violent, with twitching of muscles, sweating, cyanosis, hypertension, increased tendon reflexes, extensor plantar responses, and Cheyne-Stokes respiration. In some cases, however, the narcotic and hypotensive effects of pethidine are potentiated, and the patient has a prolonged period of unconsciousness with hypotension.⁴ In at least three cases death has been attributed to the interaction of the two drugs.⁵

An additional hazard concerns the administration of compound preparations which contain both an analgesic drug and a sympathomimetic drug such as amphetamine or one of its derivatives. The Committee on the Safety of Drugs issued a warning,⁶ directed particularly to dentists, about the dangers of using these preparations in patients who have been taking monoamine-oxidase inhibitors.

Therefore for the treatment of severe acute pain in a patient who is known to be receiving or to have recently had a monoamine-oxidase inhibitor both pethidine and compound preparations containing sympathomimetic agents should be avoided. Other narcotic analgesics may be used with caution. Morphine has been given without untoward effect to a patient who subsequently had an alarming reaction to pethidine.¹ The smallest therapeutic dose should be used and the patient watched carefully for 15 to 20 minutes after the analgesic has been given. If nothing untoward happens within this time an acute reaction is unlikely, but the patient may have a more prolonged sedative response than is usual. Should an acute

reaction occur prednisolone 25 mg. should be given intravenously. The other measure which has been recommended is the prompt acidification of the urine to increase the elimination of pethidine. The action of ammonium chloride given orally is too slow for this purpose, and the intravenous administration of sodium acid phosphate or lysine or arginine hydrochloride is suggested.⁵

Inheritance of Ankylosing Spondylitis

Q.—What are the chances of a man affected with ankylosing spondylitis having a child who will also be affected?

A.—Ankylosing spondylitis has a multifactorial aetiology, and shows a definite concentration within families. There are not enough empirical data to give a risk for the children of affected males, but data from sibs¹⁻³ indicate that the risk will be of the order of 3%, whereas the incidence in the general population is of the order of 0.5 per 1,000. The risk is likely to be higher for sons than for daughters, and higher when the mother (and not, as in this case, the father) is the affected parent.

Antidepressant Drugs and Muscular Weakness

Q.—Imipramine given for depression in a case of progressive muscular atrophy seems to increase the muscle weakness. Which group of antidepressants are least likely to affect muscle power in these cases?

A.—Muscular weakness is recognized as a side-effect which may occur in some patients treated with imipramine or other antides-

sant drugs of the dibenzepine (tricyclic) group such as amitriptyline. It is not therefore surprising that a patient with progressive muscular atrophy should respond in this way. One of the other drugs which have antidepressant properties, such as phenelzine (a monoamine-oxidase inhibitor) or a small dose of amphetamine (a sympathomimetic drug), might be tried, but it may be questioned whether in this case the use of antidepressant drugs is the correct approach to the problem. Presumably the patient's depression is secondary to his organic disease, and the response to antidepressant drugs in such cases is not likely to be as favourable as in endogenous depression.

Notes and Comments

Treatment of Chronic Brucellosis.—Surgeon Commander H. M. DARLOW (Microbiological Research Establishment, Porton, near Salisbury, Wilts) writes: The value of ampicillin in the treatment of chronic brucellosis ("Any Questions?" 30 September, p. 847) was dismissed as a failure on the strength of two cases. I have been involved with two mild and one severe case which were successfully treated with this antibiotic given in doses of 250 mg. four times a day for 28 days. The result was particularly dramatic in the severe case. The patient had been a semi-invalid for several years with frequent bouts of pyrexia and spinal changes. She has been symptom-free now for four years and leads a normal life.

While not disputing the possibility that the tetracycline-streptomycin regimen is the sheet anchor in the treatment of this distressing complaint, it is not infrequently ineffective, and one wonders if it really is superior to ampicillin or to other antibiotics and nalidixic acid, not quoted in the article, which have been used less frequently but nevertheless with some success. In view of my own experience I think that ampicillin should be given a fair trial, and I should be interested to hear through your pages of the opinions and experiences of others with this antibiotic.

OUR EXPERT replies: Claims for the success of other agents rest on reports of small numbers of individual cases such as Surgeon Commander Darlow gives. They are difficult to assess without more details of criteria, length of follow-up, and total number of patients treated. It is relatively unusual to find similar reports of individual failures, and it is unfortunate for ampicillin (which looks, on the basis of in-vitro studies, a very promising agent) that a few failures have been reported but not a few successes. Surgeon Commander Darlow is quite right: what is needed is a fair trial—if by that he means a properly conducted comparison of the tetracycline-streptomycin regimen (the only one so far submitted to extended critical examination) with other likely-looking agents.

IN ALL GRADES OF HYPERTENSION

Declinax gives firm, smooth, *comfortable* control: firm control in severe cases where the eye and kidney may already be threatened: smooth, flexible control in moderate hypertension: and *comfortable* control in mild, symptomless cases where side-effects such as explosive diarrhoea, nasal stuffiness or muscular fatigue are more trouble to the patient than the condition itself.

Book Reviews

The State, Health, and Finance

Is There an Alternative? From the *British Medical Journal*. (Pp. 73. 7s.) London: British Medical Association, 1967.

It must be assumed that the National Health Service is here to stay. Conceived in the years of depression and war to serve the poor as well as the rich, its Civil Service management is showing many signs of failure to cope with the vast and growing complexity of medical needs and developments. The extremes of poverty which it was partly designed to alleviate have now largely vanished. The advance of diagnostic technology and complex therapeutic methods are outstripping the capacity of our health service organizers to undertake the necessary rapid modernization.

Professor Henry Miller highlighted the problems in trenchant terms,¹ and his subsequent dialogue with Mr. Enoch Powell raised many questions which this collection of articles by physicians, economists, and administrators is designed to consider if not to answer. Can the basic quality of the service—indeed a great achievement—be improved? Alastair Cooke in the *Guardian*² points out the travail and troubles now besetting "Medicare" in the U.S.A., where the available service is far more uneven than in our own society. Thus national wealth, prosperity, insurance, and medical financing based on private practice cannot meet all the needs. Indeed, the affluent society has promoted by television and journalistic propaganda a public demand which it cannot now satisfy.

Lord Brain's posthumous article points out that a controlling corporation structure (like the B.B.C.) is far from a happy arrangement.

An even quality of service in all hospitals may be a political slogan but it is in practice unobtainable, especially in the smaller units which are uneconomic. Furthermore, the concentration of spearheads of knowledge, the pursuit of research, teaching, and the establishment of exemplary standards are an essential feature which must be sustained in our teaching hospitals. Without unlimited money such local concentration of selected talent is unavoidable.

Regionalization of control, possibly increasing the interest of the local public, could be helpful in one way, but it would contain within it the dangers of reversion to the intolerably low standards of the old municipal hospitals while adding to the unevenness of financial support according to the wealth or poverty of particular areas. Sir Robert Aitken, in an excellent summing up, suggests the possibility of quinquennial budgeting and delegation of independent management to the controlling regional or teaching hospital boards within the total financial allocation. He points out that university building programmes under the University Grants Committee five-year budgeting system are more effectively pursued to completion than hospital building. Such devolution of management could stimulate better attention to priorities by local awareness of relative needs than is possible by referring everything to a cumbersome, gigantic Ministry overwhelmed by its responsibilities for the regulation and control of £1,500m. annually.

Professor G. A. Duncan, a Dublin econo-

mist, points out that pools and sweepstakes as sources of extra finance make a relatively trivial contribution to costs of a health service. It is perhaps worth noting that in Britain the amount of money available for research, on which the quality and efficiency of the service will ultimately be based, is far too small, and is largely dependent on bodies external to the N.H.S. The research supporting charities and the Medical Research Council together spend about £20m. a year on such developments, while the universities, through their teaching staffs and laboratory endeavours, contribute perhaps a similar amount out of their too exiguous budgets. In an expanding and increasingly costly service these amounts, perhaps totalling 2½% of the gross N.H.S. budget, remain much too small.

Monolithic control has become too huge and unbalanced. Cross consultation between Government and the profession, though actively pursued, may fail in imagination as committees usually end in compromise and half-measures. The public remains curiously apathetic about the state of our antiquated hospitals. Until they realize from personal experience the possible misery there is little that can be done by public outcry. But those who could shout loudest still shield themselves in private and expensive comfort. Thus as a profession we have to go on with our struggle and seek the support of those who are intelligent enough to appreciate our motives and comprehend our continuing dilemmas. This book should help them.

J. McMICHAEL.

Writings of Aubrey Lewis

The State of Psychiatry. Essays and Addresses. By Sir Aubrey Lewis. (Pp. 310 +ix. 63s.) London: Routledge & Kegan Paul, 1967.

Inquiries in Psychiatry. Clinical and Social Investigations. By Sir Aubrey Lewis. (Pp. 335+vii. 63s.) London: Routledge & Kegan Paul, 1967.

In 1928 Aubrey Lewis joined the staff of the Maudsley Hospital, where later he became clinical director, director of the Institute of Psychiatry, and in 1945 professor of psychiatry in the University of London. Under his leadership the Maudsley Hospital, later combined with the Bethlem Royal Hospital, became a teaching centre known the world over. To mark the change of role to emeritus professor, his students at that time arranged the issue of these volumes containing 34 of his papers. Lewis was a prolific writer, and it was an exacting task for the editors to select material from a bibliography of over 100 articles. They have chosen well.

We have here his complete work on melancholia, covering the history, the clinical and

aetiological differentiation, and the prognostic aspects of depressive states. Running to 150 pages with almost 300 references, this in itself is a notable contribution. "The Psychopathology of Insight" was also an admirable choice. "Insight is not a word of plain and single meaning." What then does it mean? A temporary definition is offered—"a correct attitude to a morbid change in oneself"—and used as a convenient text from which to discuss the four words "correct," "attitude," "morbid," "change in oneself." All this suggests the Monday conferences at the Maudsley, so well remembered by his junior and senior colleagues.

The State of Psychiatry is in three sections: history, education, and addresses. Of the work and influence of Henry Maudsley we read: "He had something important to say on many topics that are fundamental for psychologists and psychiatrists, and he said it insistently. . . ." How true this is of Lewis himself. Among the addresses, to mention a few, we find the Manson Lecture "Philosophy and Psychiatry"; the Bradshaw Lecture "Between Guesswork and Certainty in Philosophy"; the Adolf Meyer Research Lecture "The Study of Defect"; the Hobhouse Memorial Trust Lecture

"Agents of Cultural Advance"; the Bertram Roberts Memorial Lecture (Yale University) "Ebb and Flow in Social Psychiatry"; the Harveian Oration "Medicine and the Affections of the Mind"; and by way of contrast, a B.B.C. talk "The Psychology of Shakespeare."

Inquiries in Psychiatry, covering clinical and social investigations, includes many original contributions, such as "The Experience of Time in Mental Disorder," a paper based on case records in which examples of change in the sense of time indicate significant features in psychopathology. Two papers on "Obsessional Illness" will reward the attentive reader, and so will "Demographic Aspects of Mental Disorder," delivered to a meeting of the Royal Society.

A collection of lectures and addresses cannot give continuity of theme; but this is a treatise, not a textbook, and it provides a series of well-written, well-documented studies, each in the top rank. Independent thought with clear presentation such as this is rare in psychiatric literature. We may hope that a further compilation of Lewis' work will follow.

E. A. BENNET.

Surgery in a Paperback

A Short Textbook of Surgery. By Selwyn Taylor, D.M., M.Ch., F.R.C.S., L. T. Cotton, M.Ch., F.R.C.S., and J. G. Murray, Ch.M., F.R.C.S.(Ed.). (Pp. 628+x; illustrated. 42s. Paper 30s.) London: English Universities Press. 1967.

In these days of minicars and miniskirts it was perhaps inevitable that sooner or later we should also have mini-textbooks, such as those in the University Medical Texts series, of which the latest to appear is *A Short Textbook of Surgery*, by Selwyn Taylor, Leonard Cotton, and Greig Murray. At first sight it might seem hard to believe that this slim volume—a paperback, corresponding in size to two Penguins with rather larger pages, and costing only 30s.—could adequately fulfil the authors' ambition to provide a complete text for undergraduates and practitioners. But, almost miraculously, it does, and very thoroughly too on all aspects of surgery (except E.N.T. and eye surgery and anaesthetics). This feat has been achieved by dint of very succinct and readable writing and by the sparing use of illustrations, all 87 of which are simple line-drawings. Moreover, for the guidance of those who wish to pursue various subjects farther, there are helpful references to specialist texts at the end of many of the chapters.

The result is a most refreshing book which cannot fail to give students a modern view of surgery likely to arouse their interest. Whether it will achieve its declared objective of establishing the habit whereby students will buy a cheap disposable text of this kind and discard it in favour of a newer edition every few years is less certain. For the tradition by which a student purchases a textbook at the beginning of his undergraduate clinical career and continues to rely on it, with supplementary reading, for the rest of his professional life is deeply ingrained. But this short textbook is unquestionably one of the most

exciting developments in the field of textbook publishing and I wish it every success.

J. C. GOLIGHER.

Panorama of Internal Medicine

Cecil-Loeb Textbook of Medicine. 12th edition. Edited by Paul B. Beeson, M.D., and Walsh McDermott, M.D. (Pp. 1738+xxxix+liv; illustrated. Single volume £7 3s. 6d. Two-volume set £8 11s. 6d. De luxe edition £10 10s.) London: W. B. Saunders. 1967.

There are many who believe that the day of the large textbook of medicine is past. They acknowledge, of course, that undergraduates and family doctors (who are supposed to know something about everything) require a concise text containing the essentials of medicine as a framework on which to build their knowledge. Such a book should be cheap, and, owing to the fantastically rapid advance of medical science, new editions of it should appear every two or three years. When knowledge in depth of any subject is required, however, they think it should be studied in monographs and original papers rather than in large textbooks which are bound in some respects to become out of date in a few years, and sometimes even in the considerable period which must elapse during the slow, elaborate process of their publication. There must be many who disagree with these views, for the demand for large and very large textbooks of medicine seems to be greater than ever.

This is the twelfth edition in 40 years of this immense lexicon which surveys the whole panorama of internal medicine, including dermatology and the psychoses. Dr. Cecil (who died in 1965) and Dr. Loeb made the

work famous, and, after the 10th edition, handed on the editorial torch to Dr. Paul Beeson (now Nuffield Professor at Oxford) and Dr. Walsh McDermott, of Cornell, assisted by five associate editors. They have chosen 169 contributors, 52 of whom are new to this edition so that much of it has been entirely rewritten. Apart from Sir Aubrey Lewis, of the Maudsley, and Professor Ronald Christie, of McGill, the contributors are all drawn from American schools and represent a large proportion of the flower of its medicine. The book weighs some 6 lb. (or 3 kg., as we should say nowadays), and like a great, handsome family bible is somewhat unwieldy to handle, but is available, at greater expense, in two more manageable volumes. It is none the less 100 pages shorter than its predecessor—no mean editorial achievement—but is seven shillings dearer, which roughly represents the rise in the cost of living in four years.

It is unlikely that many doctors will buy a new expensive edition of Cecil and Loeb every time one is published; they will prefer to consult it as an authoritative work of reference in libraries and university departments, which should always possess a copy. Nevertheless, there is much in medicine which is not ephemeral, and the possession of any edition of this book will be of permanent value to any doctor. It would be an affectation to pretend that I have perused more than the few portions of it with the contents of which I can still claim a slight nodding acquaintance, but I have found those parts which I have studied to be impressively authoritative, discriminating, wise, and up to date. One of the forewords by Dr. Atchley—sometime of the Presbyterian Hospital—on patient-physician communication would repay reading by all medical men. This probably represents the best great textbook of medicine in the English language.

DERRICK DUNLOP.

Books Received

Review is not precluded by notice here of books recently received.

A Short Textbook of Psychiatry. By W. L. Linford Rees, B.Sc., M.D., F.R.C.P., D.P.M. (Pp. 305+x; illustrated. 35s. Paper 25s.) London: English Universities Press. 1967.

Feminine Psychology. By Karen Horney. Edited and with an Introduction by Harold Kelman, M.D. (Pp. 269. 30s.) London: Routledge & Kegan Paul. 1967.

Science and E.S.P. Edited by J. R. Smythies. (306+viii. 42s.) London: Routledge & Kegan Paul. 1967.

The Know-How of Infant Care. By Sylvia Close, S.A.N.C.Med. and Surg.(Hons.), S.A.N.C. Midwifery(Hons.). (Pp. 49. 5s.) Bristol: John Wright. 1967.

L'Année Endocrinologique. 19th year. By M. Albeaux-Fernet, L. Bellot, L. Canet, J. Deribieux, M. Gelinet, and J. D. Romani. (Pp. 215. 42 F.) Paris: Masson. 1967.

Ganglion-Blocking and Ganglion-Stimulating Agents. By Professor D. A. Kharkevich. Translated by Dr. R. Crawford. Edited by W. D. M. Paton. (Pp. 367+xi; illustrated. 90s.) Oxford: Pergamon. 1967.

GENERAL PRACTICE OBSERVED

Survey of General-practitioner Maternity Units in England and Wales

M. S. T. HOBBS,* M.B., M.R.A.C.P.

Brit. med. J., 1967, 4, 287-290

This paper is one of a series describing an investigation into the organization of the obstetric services in England and Wales (Acheson and Feldstein, 1964; Hobbs and Acheson, 1966a, 1966b). Previous studies in the series had shown that in the Oxford area general-practitioner maternity units are used as an alternative to consultant care for mothers with both high and low risks of perinatal mortality. Furthermore, the proportion of high-risk mothers booked for consultant care decreases sharply as the distance from the nearest consultant unit increases when general-practitioner beds are available as an alternative, but no similar decrease is observed when such beds are not available. Though the number of G.P. units in the area available for study was small, there was a suggestion that the proportion of high-risk mothers selected for delivery in consultant units was greater when the G.P. beds were incorporated in a consultant unit or when the G.P. unit was visited regularly by a consultant for antenatal consultations. In view of the possible implications of these findings for planners of the maternity services, it was felt that additional information about G.P. maternity units should be obtained from a national survey.

The objectives of the survey were as follows: (1) to examine the geographical relation of G.P. units to consultant units; (2) to examine the extent to which direct liaison exists between consultant maternity units and G.P. maternity units for selection of cases, provision of antenatal care, and management of complications in labour; and (3) to assess the standard of equipment and other facilities of G.P. maternity units necessary to deal with obstetric emergencies and resuscitation of the newborn.

Material and Method

In 14 of the 15 hospital regions of England and Wales the permission of the senior administrative officer was obtained to send postal questionnaires to the G.P. maternity units within the region. Permission was granted to send these direct to the matrons in seven regions, and through the group secretaries concerned in six regions, with the request that the forms be completed with the assistance of the matrons. In the remaining region completion of the forms was undertaken by the regional hospital board concerned.

Replies were received from 274 of the 288 units to which the form was sent. The information recorded on the forms was transferred to 80-column punch cards, and the subsequent

analyses were carried out with the aid of standard business machines.

Geographical Relation of G.P. Units to Consultant Units

Distance from Nearest Consultant Unit.—In Fig. 1 the distribution of units by distance measured in miles from the nearest consultant unit is shown. Eight units (2.9%) were completely integrated with consultant units, and five further units (1.8%) were situated at distances of less than half a mile (800 m.) from the nearest consultant unit, making a total of 13 (4.7%) situated in close proximity to a consultant unit. Seventy-five units (27.4%) were situated from half to five miles (0.8 to 8 km.) distance, 66 (24.1%) from 5 to 10 miles distance (8 to 16 km.), and the remaining 120 units (43.8%) were situated more than 10 miles from the nearest consultant unit.

FIG. 1.—Distribution of G.P. maternity units according to distance in miles from the nearest consultant unit.

This finding suggests that in a large proportion of G.P. units a considerable interval may elapse when it is necessary to transfer obstetric emergencies to consultant units. Correct initial selection to avoid such situations is therefore of great importance.

Contact with Consultant Obstetricians

In G.P. units which are physically integrated with consultant units on the same site close liaison between consultants and general practitioners using the units can be assumed to exist. The analyses which follow are therefore confined to the remainder—that is, the self-contained general-practitioner maternity units.

Contact in Antenatal Period

The inquiry was directed towards determining in which units (i) a consultant obstetrician is responsible for selecting cases for delivery in the unit; (ii) a consultant reviews the progress of all women selected for delivery in the unit in late pregnancy; (iii) a consultant visits antenatal clinics held at the unit to review complicated cases only; and (iv) no special arrangement for consultation exists apart from the referral of the complicated case to a consultant antenatal clinic by the G.P.

The extent to which units have some special arrangement for consultant obstetricians to see cases in the antenatal period—that is, i-iii—referred to as “consultant contact during the antenatal period,” is shown in Fig. 2. In 66 units (24.8%) a consultant obstetrician selects the cases to be delivered in the unit and also reviews their progress at a later stage of pregnancy. In a further 17 units (6.4%) the consultant selects the cases for delivery in the units but reviews only those with complications of pregnancy. In 15 units (5.6%) selection for delivery is made by general practitioners, but the consultant reviews all cases at least once during pregnancy. A consultant obstetrician thus sees all cases at some stages of pregnancy in 36.8% of units. In a further 54 units (20.3%) a consultant obstetrician visits the unit antenatal clinic to see complicated cases selected by the general practitioner. In the remaining 114 units (42.9%) no special arrangements exist between consultants and general practitioners for contact in the antenatal period.

Fig. 2.—Distribution of self-contained G.P. units according to type of arrangements which exist for contact with a consultant obstetrician in the antenatal period.

Factors affecting consultant contact in the antenatal period:

(a) *Existence of Antenatal Clinics.*—The relation between the existence of antenatal clinics and the frequency of consultant contact in the antenatal period is shown in Table I. Of the 266 units 140 (52.6%) have antenatal clinics supervised by medical practitioners. (A further 22 units have antenatal or booking clinics supervised by midwives alone which have been excluded from this group.) In these a consultant sees all mothers for selection or review in 56 (40.0%) and visits to see complicated cases selected by the general practitioner in a further 54 (38.6%). Consultant contact during the antenatal period thus exists in 78.6% of units with antenatal clinics. In contrast, only 42 (33.3%) of the 126 units without clinics have formal arrangements whereby mothers visit a consultant clinic elsewhere for selection or review. The difference, which is significant at the 0.001 level, strongly suggests that the existence of antenatal clinics may be an important factor in determining whether or not units have close liaison with a consultant in the antenatal period. Moreover, the opportunity for personal contact between consultants and general practitioners should be much greater where consultants visit G.P. units than in the case where mothers attend a special consultant clinic elsewhere. However, it is notable that of the units with antenatal clinics 22 (15.7%) had clinics attended by a consultant only, and that in only 18 (12.9%) did all general practitioners using the unit also attend the antenatal clinics. Personal contact between consultant and general practitioner is therefore by no means certain even in the

units visited by a consultant. Nevertheless, the finding that only 52.6% of units have antenatal clinics is unsatisfactory.

TABLE I.—Relation Between Consultant Contact in the Antenatal Period and the Existence of Antenatal Clinics in Self-contained G.P. Maternity Units

Nature of Contact	Units with Antenatal Clinics		Units without Antenatal Clinics		All Units	
	No.	%	No.	%	No.	%
Consultant selects or reviews all cases for delivery in G.P. unit	56	40.0	42	33.3	98	36.8
Consultant visits antenatal clinic at G.P. unit to see complicated cases	54	38.6	—	—	54	20.3
No special arrangement for consultant to see cases	30	21.4	84	66.7	114	42.9
Total	140	100.0	126	100.0	266	100.0

(b) *Regional Differences.*—In Table II the hospital regions have been ranked according to the proportion of units with special arrangements for consultant contact in the antenatal period. Because of the small number of units in many regions categories 1–4 in Fig. 2 have been here grouped together. Consultant contact for antenatal care is seen to range from 82.3% for region A to 33.3% for region N. This considerable variation suggests that there may be important differences between the regions in policy regarding the relation between consultant obstetricians and general-practitioner maternity units.

TABLE II.—Proportion of Self-contained G.P. Maternity Units with Special Arrangement for Consultant Contact in the Antenatal Period in 14 Hospital Regions in England and Wales

Hospital Region	All Units	Units with Consultant Contact in Antenatal Period	
		No.	%
A	34	28	82.3
B	4	3	75.0
C	30	21	70.0
D	13	9	69.2
E	3	2	66.6
F	28	17	60.7
G	18	10	55.5
H	19	10	52.6
I	25	13	52.0
J	10	5	50.0
K	11	5	45.4
L	9	4	44.4
M	47	20	42.6
N	15	5	33.3
All regions	266	152	57.1

(c) *Distance from Nearest Consultant Unit.*—When the effect of the distance in miles from the nearest consultant unit on consultant contact in the antenatal period was examined it was found that there were no important differences between those units nearest a consultant unit and those most distant.

Consultant Contact During Labour

In addition to questions about the extent to which consultants are involved in antenatal supervision, an inquiry was made whether a consultant obstetrician (other than with the flying squad) visits the unit to see complicated cases during delivery (referred to as “contact during labour”). A positive answer to this question was given in 197 units (74.1%).

The extent to which consultant contact during labour and contact in the antenatal period are related is shown in Table III.

TABLE III.—Relation Between Consultant Contact in the Antenatal Period and for the Management of Complications of Delivery

	Consultant Contact in Antenatal Period	No Consultant Contact in Antenatal Period	All Units
Consultant visits to see complicated cases in labour	127 (64.5%)	70 (35.5%)	197 (100%)
Consultant does not visit to see complicated cases in labour	25 (36.2%)	44 (63.8%)	69 (100%)
All units	152 (57.1%)	114 (42.9%)	266 (100%)

Special arrangements for consultant contact in the antenatal period exist at 127 (64.5%) of the units where a consultant visits to see complicated cases in labour, but in only 25 (36.2%) of the units where such visits are not made. This difference, which is highly significant ($\chi^2=12.77$; d.f.=1; $P<0.001$), indicates that consultant contact during labour and contact in the antenatal period are closely related.

The effect of distance on consultant contact during labour is shown in Fig. 3. It is seen that consultant contact decreases from 80.09% when units are less than five miles (8 km.) from the consultant unit to 52.9% when over 15 miles (24 km.) distant. In contrast to contact between consultant and G.P. units for antenatal care it is thus seen that consultants visit less often to see complicated cases during labour as the distance

FIG. 3.—Proportion of self-contained G.P. maternity units with consultant contact during labour according to distance in miles from the nearest consultant unit.

increases. This finding, which is statistically significant ($\chi^2=9.44$; d.f.=3; $0.05>P>0.02$), emphasizes the importance of correct selection of mothers for delivery in those units most distant from a consultant unit.

Equipment and Facilities for Management of Obstetric Emergencies

General Anaesthesia

A detailed inquiry was made about anaesthetic equipment. The actual value of such equipment obviously depends on all items required for a particular technique being available. A points score for anaesthetic facilities has therefore been constructed with the advice of a consultant anaesthetist which takes into account both the functional effectiveness of the equipment and the quality of the anaesthesia that could be administered. With regard to the latter, the advice that we received stressed the fact that, while mothers were in general young and healthy, the mechanical problems of pregnancy may make the administration of anaesthetics particularly difficult. Ideally they should only be undertaken when the following facilities are available: (a) adequate suction; (b) a table (or bed) which can be tilted to the head-down position; and (c) equipment for intubation and controlled ventilation.

Of the above, mechanical suction is virtually mandatory, but provided this is available general anaesthesia may be given in emergencies with either an anaesthetic machine and face-mask or an open anaesthetic mask. Following these principles points were allotted as follows:

Equipment	Points
(1) Mechanical suction	2
(2) Complete equipment for intubation anaesthesia (including laryngoscope, endotracheal tubes, rubber face-mask, bag and connexions, anaesthetic machine)	2
(3) Access to operating-theatre* (or operating-table)	1
(4) Anaesthetic machine plus rubber face-mask, bag and connexions, or open anaesthetic mask	1

* This question was intended to identify units where patients could be tilted to the head-down position. Unfortunately it does not take into account units with obstetric beds which can be tilted head down. Units with such beds may thus be underscored in this respect.

The total points score possible is five. Examples of possible scores are as follows:

Equipment	Score
Intubation anaesthesia, suction, tilting table	5
Intubation anaesthesia and suction, or simple machine anaesthesia (or open anaesthesia) plus suction and tilting table	4
Simple machine anaesthesia (or open anaesthesia) plus suction	3
Simple machine anaesthesia (or open) plus tilting table	2
Simple machine anaesthesia (or open) alone	1

It will be noted that units with a score of less than 3 do not possess suction equipment. Their equipment is therefore inadequate for safe anaesthesia. A score of 3 indicates minimal facilities for safe anaesthesia, a score of 4 indicates good facilities, while 5 indicates optimum facilities. The distribution of anaesthetic facilities classified in this way is as shown in Table IV. In 57 of the units (21.4%) no adequate facilities for general anaesthesia were available.

TABLE IV.—Distribution of Anaesthetic Scores for Self-contained G.P. Maternity Units

Anaesthetic Facilities	Score	No. of Units	% of Units
Inadequate	0-2 points	57	21.4
Minimal	3	39	14.7
Good	4	90	33.8
Optimal	5	80	30.1
All		266	100.0

When anaesthetic scores were examined according to whether or not units had contact with a consultant for intrapartum complications (Fig. 4) it was found that in units with consultant contact the facilities were inadequate or minimal in 30.1% of units and good or ideal in 69.9%. In units without contact the facilities were inadequate or minimal in 52.2% (for the differences in anaesthetic facilities $\chi^2=9.73$; d.f.=1; $0.01>P>0.001$). Similar but less marked differences in anaesthetic facilities were observed according to whether or not units had consultant contact for antenatal care.

FIG. 4.—Distribution of anaesthetic facilities scores for self-contained G.P. units with and without consultant contact during labour.

Care of Newborn

Several questions relating to the care of the newborn were asked in the inquiry. These included questions about nursery facilities, visits from consultant paediatricians, and equipment for the resuscitation of the newborn. In this paper, however, attention is confined to equipment for resuscitation of the newborn, which was thought to be the most important aspect of this part of the inquiry.

The general introduction of intubation and controlled respiration for the resuscitation of anoxic babies has been in

significant advance in the care of the newborn (Hodges *et al.*, 1963; Barrie, 1963). Moreover, as both the technique and equipment required are simple, it should be possible for this method of resuscitation to be used in G.P. units should the occasion arise.

Units were considered to have equipment for intubation of newborn when both infant endotracheal tubes and a laryngoscope were available (whether infant or adult). This equipment was not available in 34.0% of units. When assessed in relation to contact with consultant obstetricians it was found that equipment for intubating the newborn was present in 57.1% of units with contact during labour, but in only 52.2% of those without contact ($\chi^2=6.49$; d.f. = 1; $0.02>P>0.01$).

Access to Operating-theatres

A total of 106 units (39.8%) were stated to have access to an operating-theatre. The proportion of such units visited by a consultant to see complicated cases during labour, 78.3%, was significantly greater than those without access to an operating-theatre, 71.8%, but this difference is not statistically significant.

Obstetric Equipment

No relation was found between the possession by units of various items of obstetric equipment and visits by a consultant to see complicated cases during labour.

Discussion

The importance of a close working relation between G.P. maternity units and consultant obstetricians has been stressed by many authorities (Ministry of Health, 1959; Baird, 1960; C.O.G., 1962; Stallworthy, 1964; Stirling, 1963). That such arrangements are not only desirable but may also be essential has also been emphasized by general practitioners who have had first-hand experience of working in units with a consultant liaison (Jameson and Handfield-Jones, 1954; Jameson, 1961; Stewart-Hess and Green, 1962). It is therefore not surprising that in almost half (42.9%) of the self-contained G.P. units in England and Wales in 1966 there was no special arrangement for a consultant obstetrician to see during pregnancy mothers booked for delivery in the units. The absence of facilities to contact antenatal clinics appears to be one important factor underlying this finding; differences between regional hospital boards in policy regarding the relation between consultant obstetricians and G.P. maternity units may be another.

Under the hospital plan announced by the Ministry of Health (1962) it is envisaged that the majority of G.P. maternity beds will eventually be incorporated in district hospitals, where close co-operation between consultants and general practitioners should be the rule. However, in 1966 fewer than one in 30 G.P. units were physically integrated with a consultant unit, and it thus seems likely that it will be many years before this ideal is achieved. It therefore seems important that in the meantime steps should be taken to ensure that all G.P. units have the facilities to conduct antenatal clinics, and that there should be a policy whereby these are visited regularly by a consultant obstetrician to see complicated cases and to advise on the selection of cases suitable for delivery in the unit.

Another matter of policy raised by this survey is the quality of equipment and facilities required in G.P. units for dealing with obstetric and paediatric emergencies. There can be little doubt that all units should contain efficient equipment for the resuscitation of the newborn, but in the matter of anaesthetic

and obstetric equipment the issues are less clear. Many authorities may feel that G.P. maternity units have no need of sophisticated equipment, as emergencies are now efficiently and safely dealt with by transfer to a consultant clinic. On the other hand, the delays involved in transferring such cases may in some instances make this course impracticable or more hazardous. Local circumstances rather than a general rule should therefore direct what is desirable in the type of anaesthetic and obstetric equipment in G.P. units. It is nevertheless of considerable interest that the quality of equipment is related to whether or not a consultant visits the unit to see complicated cases in labour.

Summary and Conclusions

This paper reports the results of a national postal survey of general-practitioner maternity units, involving 274 (95%) of the 288 units to whom the questionnaire was sent. The following are the main findings:

(1) About one in 20 (4.7%) of the units are integrated with or in close proximity to consultant units. Almost half (43.8%) are situated more than 10 miles (16 km.) from such units. As transfer of obstetric emergencies from such units is likely to involve considerable delay, selection of low-risk mothers for delivery there is of obvious importance.

(2) When the degree of contact between the units and consultant obstetricians was examined it was found that in almost half (42.9%) there was no formal arrangement for antenatal consultation with a consultant obstetrician. However, in nearly three-quarters of the units (74.1%) a consultant visited to see complicated cases during labour.

(3) The frequency of formal arrangements whereby a consultant sees cases antenatally was found to be associated with the existence of antenatal clinics. Three-quarters of the units with antenatal clinics had an arrangement, while one-third of units without clinics had no such arrangement.

(4) When the equipment of the units was studied it was found that about one in five (21.4%) did not have facilities to give an anaesthetic safely and one in three (34%) did not have equipment for intubating the newborn. The likelihood of possessing both types of equipment was associated significantly with an arrangement for a consultant to visit during labour.

(5) These findings suggest that in self-contained G.P. maternity units both formal arrangements for contact with a consultant obstetrician and the existence of antenatal clinics are highly desirable.

I wish to thank the senior administrative medical officers of the hospital regions in England and Wales for their permission to conduct this survey, the matrons and group secretaries of the units concerned for their co-operation in completing the questionnaires, Dr. D. C. Hodgson for his advice in constructing the anaesthetic equipment scores, and Dr. E. D. Acheson for his advice in the design of the survey and preparation of this paper.

Medical Management in Hospitals

In December 1965 the Secretary of State for Scotland set up a Working Party of doctors and hospital service administrators "to consider what developments in the hospital service are desirable in order to promote efficiency in the organization of medical work." In 1966 a Joint Working Party was appointed by the Ministry of Health and the Joint Consultants' Committee with the same terms of reference. The two Working Parties have published their first reports^{1,2} this week. Printed below is a summary of the recommendations.

Scotland*

The Working Party set up subgroups to consider four aspects of the subject—namely, clinical organization and staff committee systems, medical staffing, alternatives to traditional systems of hospital care, and operational research. The parent Working Party nevertheless makes it clear that it could not consider hospital work in isolation from the other branches of the N.H.S., and it recommends that the Secretary of State should set up another Joint Working Party with wider terms of reference to consider the organization of medical work in the N.H.S. as a whole.

Within the hospital service the report proposes that clinical organization should be based on larger groups than at present. The new administrative entity proposed is the "division" made up of "consultancies" consisting of a consultant and that part of the hospital staff and resources available to him. Divisions would be formed by the grouping together of specialties falling into the same broad categories, such as general surgery, the laboratory services, and so on. Divisions should organize and encourage evaluation of the care of patients and would also co-ordinate the use and the training of hospital junior staff. The chairmen of all divisions within a hospital should form a committee to deal with professional matters concerning the interest of more than one division or the hospital as a whole. This committee of chairmen would be able to give advice to the regional hospital board. Clinical staff at all levels of training should receive guidance in organization and administration.

Medical Staff

The shortage of medical manpower was being accentuated by emigration, says the report, and no increase in output could be expected from medical schools in the next 10 years. The morale of junior staff had

been affected by the anxiety felt by registrars about their career prospects. The report recommends that a planned registrar establishment should be created related to career prospects in the N.H.S. The reduction of the registrar establishment made necessary by this change would be made up by an increase in the numbers of medical assistants. The report warns against the possibility of medical assistants carrying out work with specialist responsibility, and also draws attention to the disincentive for general practitioners to undertake sessional work as part-time medical assistants under present financial arrangements.

More effective use of medical manpower can also be made by the provision of adequate secretarial assistance, says the report, and the provision of adequate numbers of ancillary staff should be the subject of urgent attention.

Alternative Systems of Hospital Care

Hospital care based on medical "firms" and the retention of patients in the same ward at all stages of illness lead to inefficiencies, suggests the Working Party. The report advocates the separation of beds for emergency cases from those for patients on the waiting-list. A number of beds would be allocated for routine admission, investigation, and treatment of patients, and their time of admission and length of stay in hospital planned in advance. Patients admitted in this way should reach hospital only after all possible investigations and treatment which could be carried out as an outpatient had been completed. The report also recommends that the advantages and disadvantages of techniques used in routine investigations should be examined.

The Working Party recommends that acute beds should be divided into intensive nursing care beds, intensive therapy beds, and short-stay beds. This last category would include overnight and observation beds and five-day beds, which could be used to accommodate patients whose condition could be investigated and treated during the course of a five-day week. These beds could close at week-ends, which would facilitate their staffing by part-time married nurses. Planned early discharge could be made easier by co-operation between hospital, general practitioner, and local authority services.

Operational Research

The report asserts that effective use of limited resources can be made only after operational research has been carried out, and that clinicians should be presented with readily intelligible accounts of work

done. An evaluation of patient care should be introduced and studies undertaken to find out what modifications to American techniques may be necessary.

The Working Party proposes to continue its meetings and to issue a further report. Implementation of the present proposals will require consultation among all concerned, but the report recommends that immediate steps be taken to work out the planned registrar establishment and its introduction with the agreement of the profession and the hospital authorities.

England and Wales†

The English Joint Working Party's report is concerned mainly with the reform of the clinical organization of medical staff in hospitals and hospital groups. This report, like that from Scotland, recommends the grouping together of categories of specialties to form divisions. Each division would have a chairman, and a small medical executive committee would be formed in each hospital with representatives from each division. The chairman of the executive committee would have time for administrative duties included in his contract. Chairmen of divisions and of the executive committees would be appointed by boards of governors or by regional boards in consultation with hospital management committees and consultant staff. (This contrasts with the recommendations of the Scottish report, which suggests that chairmen of divisions should be elected by their colleagues.) The chairman of the executive committee would be an experienced clinician, but he would act in his administrative capacity for five years or more. He would be the chief medical spokesman of the hospital in its relationship with the regional board and would speak for medical staff to other bodies. The report makes it clear, however, that it does not propose to resurrect the medical superintendent. (In Scotland, where medical superintendents have been retained, no post of chairman of executive committee has been proposed.) The functions of the executive committee will be to receive reports from divisions, to consider medical policy in planning, and to co-ordinate the medical activities within the hospital.

The report suggests that hospitals should go ahead with reorganization. It envisages that staff accommodation will be needed by the divisions and executive committee and that chairmen of the executive committees and other medical staff will need training in administration.

Obstetric Forceps or Vacuum Extractor?

SIR,—Your leading article on the above subject (23 September, p. 753) has just come to my notice. Although it appears to be based on the paper by Schenken and Serr,¹ the conclusions which it draws seem to be wholly at variance with those of the authors quoted.

This paper deals with a study of some 300 cases delivered with the vacuum extractor compared with a similar number delivered with forceps. Foetal distress was the indication in 10% of the vacuum-extractor cases and 29.6% in the forceps cases, the difference not being significant. In 10 cases foetal distress increased during the delivery with the vacuum extractor partly because of absolute or relative shortness of the second stage. In our experience this change of opinion would appear to have been unfounded. Much has been made of the slow rate of extraction with the vacuum extractor, but in the series quoted the duration of extraction was less than 20 minutes in more than half of the cases, and in four did it reach 20 minutes. The authors show that in the vacuum extractor series 10% of the cases in 300 died. In two of these intracranial haemorrhage was the cause and in both cases traction was prolonged beyond 20 minutes. In the forceps series seven infants died and in four of these cerebral haemorrhage and tentorial lacerations were found. There was evidence of central nervous system damage in 1% of the vacuum-extractor series and 1.3% of the forceps series. The frequency of cephalohaematoma and scalp laceration was the same in both groups, and 95% of these cleared up within five days. In the forceps series there were four facial palsies and one fractured skull. No similar lesions were found in the vacuum-extractor group.

In view of the above figures it is quite clear that the danger to the foetus of forceps delivery is greater than that of vacuum extraction. Your suggestion that forceps delivery would be quicker is probably true, but I would deny absolutely that the preparations for the use of the vacuum extractor take at least a quarter of an hour. Many of our cases have been delivered within five minutes of setting out to rescue a distressed child, and with the recent use of the Einar Egnell vacuum pump we have been able to produce an adequate chignon on the scalp within two to three minutes and to complete the delivery very rapidly thereafter. Schenken and Serr have shown clearly the danger of attempting delivery in a high station in the pelvis and of prolonged traction. We believe that where the head lies more than one fingerbreadth above the ischial spines caesarean section is the better alternative and that delivery from a high station is unjustifiable in present-day obstetrics. The argument that the position of the occiput should be checked before forceps is applied applies equally to the application of the vacuum extractor. The results of failure to orient the head exactly are much

more likely to be disastrous with the forceps than with the vacuum extractor, and it must be reiterated that a failed vacuum extraction cannot be equated with a failed forceps operation. I would agree that properly applied obstetric forceps should not damage the brain, but in the series quoted brain damage, fatal or non-fatal, was materially more frequent in the forceps group than in the vacuum-extractor series, and our results here in over 1,000 vacuum extractions confirm the much greater safety of the vacuum extractor. Furthermore, in malrotation of the occiput the vacuum extractor can achieve rotation of the head from either the occipito-posterior or transverse position very much more easily than can forceps or manual rotation, with increased safety for both mother and child.

In view of the foregoing figures derived from the article you have reviewed, your conclusion that the vacuum extractor has no place on the district or a general-practitioner maternity unit is very difficult to understand. The place of instrumental delivery in domiciliary obstetrics and in the general-practitioner maternity unit must always be limited, and present conditions throughout most of this country indicate that all but the simplest instrumental deliveries, whether by vacuum extractor or other means, should be carried out in a specialist unit. Even in this country, however, there are remote areas where this is not practicable, and in parts of the world less generously equipped with hospitals this applies even more strongly, and so intervention has to be undertaken outside a specialist unit. Where this is the case, we believe that the vacuum extractor is safer for the mother, since there is less need for general anaesthesia, less risk of introducing ascending infection, and less risk of trauma to the vagina and cervix. It is safer for the child in that there is less risk of intracranial trauma and less likelihood of applying excessive traction than with the forceps. The figures of the foetal trauma quoted by Schenken and Serr (who as you point out are practising obstetricians) show that even in the hands of the specialist intervention with the head high in the pelvis carries a considerable risk, and except in the case of a second twin almost all such cases are better dealt with by caesarean section. Where the head is little above mid-cavity, however, the vacuum extractor can be used by the experienced obstetrician effectively and safely and even the occasional operator is likely to do much less harm with this than with the forceps. For this reason I would disagree completely with your conclusion about the place of the vacuum extractor outside the specialist unit. I would not wish to advocate heroic use of this or any other instrument, but in properly selected cases it has been shown by Cavenagh² that it can

make a very real contribution to the work of the general practitioner.—I am, etc.,

J. A. CHALMERS.

SIR,—I should like to express my most profound disagreement with some of the views in your leading article on the vacuum extractor (23 September, p. 753).

I have used the vacuum extractor in over 60 domiciliary deliveries in general practice. In no case has there been a stillbirth, neonatal death, or any evidence of cerebral injury. In a few cases there have been small lacerations of the scalp due to the use of the smallest cup, not to prolonged traction. I have not used forceps in domiciliary deliveries for many years. I use the vacuum extractor to prevent delay or foetal distress in the second stage. This is accomplished by applying the instrument after one hour in primigravida and 20 minutes in multigravida unless delivery is imminent.

You state that delivery with forceps will be quicker than with the vacuum extractor; this ignores the time required for getting an anaesthetist and giving an anaesthetic or alternatively using some form of local or spinal anaesthetic. The vacuum extractor can be used without an anaesthetic, so that unless the patient was already anaesthetized the vacuum extractor would be the quicker instrument to use.

"Secondly, delivery is safer because a doctor cannot hope to apply the forceps correctly. . . ." The operative word here is "hope." Surely one hopes to apply the cup correctly too. If one's hopes are not matched by one's achievements a failed or difficult vacuum extraction is less likely to injure the foetus than a failed or difficult forceps delivery.

Your penultimate paragraph is the most insulting I have read for a long time. Your writer ignores the fact that a large number of general practitioners are highly skilled obstetricians. A few are members and a great number diplomates of the Royal College of Obstetricians and Gynaecologists. It is surely ridiculous to suggest that an obstetric house-officer is more competent than an experienced obstetrician who uses his skill in the sphere of general practice.—I am, etc.,

Croydon, Surrey.

THOMAS WHITE.

SIR,—Your leading article on obstetric forceps or vacuum extractor (23 September, p. 753) raises many debatable points. I will confine myself to comment on a few. Generalizations seem inappropriate in the discussion of the relative merits of these two important obstetric tools.

What is meant by foetal distress? The degree of distress will obviously influence the method of delivery, and so will the location

of the patient at the time. What is a trained obstetrician? Is he the same as "a doctor," referred to in the next sentence, or "a general practitioner obstetrician," referred to in the final sentence.

By amalgamating the two indications for assisted delivery—that is, delay and distress—the writer of your leader confuses the issue. Most obstetricians would agree that forceps delivery is preferable to vacuum extraction in cases where rapid delivery is required in the second stage of labour, when foetal distress occurs with the foetal head fully engaged, because there is no doubt that the application of and delivery with the vacuum extractor does take longer than forceps delivery. However, delivery does not require to be excessively rapid if there is no foetal distress, so the question arises whether forceps delivery is really preferable to vacuum extraction for delay in advance of the foetal head in the second stage of labour. My own experience leads me to doubt it, even though I feel that my skill with the obstetric forceps is at least average.

The statement is made that "delivery is safer [with forceps] because a doctor cannot hope to apply the forceps correctly and effectively until he has checked the position of the occiput," and that "properly applied obstetric forceps should not damage the brain." Not all general practitioners are skilled in assessing the position of the occiput from pelvic examination, and fewer still have the necessary experience and skill to correct malpositions of the foetal head. The doctor who cannot diagnose occipito-posterior position of the occiput from his pelvic examination (and this is by no means always easy to the expert, in the presence of a large caput and deep engagement of the foetal head) will be an even greater menace to the unborn child with faulty application and attempted delivery with forceps than he would be with an attempted vacuum delivery, even if the latter fails, provided that he uses the vacuum only to assist uterine contractions and associated maternal effort, and is prepared to desist from any further attempts at delivery if this has not been effected within 20 minutes. Most of the misfortunes attributed to the vacuum extractor have been due to impatience or unduly prolonged application of the vacuum in cases where minor disproportion exists.

I would dispute the leader writer's conclusion that "the vacuum extractor has no place . . . in a general practitioner maternity unit." Given the assurances indicated above, I feel that it can be a safer instrument than forceps in the hands of the relatively inexperienced obstetrician.—I am, etc.,

W. H. LAIRD.

SIR,—Your leading article (23 September, p. 753) on the use of the vacuum extractor and the obstetrical forceps states that neither instrumental technique has any place if the foetal head is not engaged in the pelvis. In the delivery of a second twin with the vertex presenting, where foetal distress occurs, may not the vacuum extractor cup be applied to a head which is not engaged and delivery be expedited? If necessary, external pressure might be applied to the uterine fundus to fix the head. This method of delivering a

second twin in such a case may be safer than version and breech extraction, and quicker than caesarean section.—I am, etc.,

Psychotropic Drugs

SIR,—As one of the senior registrars at St. Thomas's my views on the efficacy of the monoamine-oxidase inhibitor drugs may be regarded as prejudiced, but I feel there is something helpful that I can add to the controversy (30 September, p. 861, and 14 October, p. 108).

When I first started my psychiatric training in 1962, in a Bristol hospital, Parstelin (tranylcypromine and trifluoperazine) was being widely used there in the treatment of non-endogenous, neurotic-type depression, and I had no doubt that this was an effective drug in this type of illness. When its use was curtailed there by the cheese-reaction scare the loss of this valuable drug was very noticeable clinically. I then moved to another teaching hospital in London, where, although isocarboxazid was sometimes used, Parstelin was regarded as too dangerous and phenelzine deemed useless.

On taking up my present post two years ago I of course knew that Dr. W. W. Sargent and others regarded phenelzine and the other monoamine-oxidase inhibitor group as very useful drugs in selected patients, but I must admit that at that time I had now become sceptical of their value from what I had been taught. However, I again started to see, as I had done in Bristol, many patients with quite long histories who had failed to respond to other treatments show quite remarkable improvement, but what was even more surprising was the large number of patients with phobic anxiety states improving on the phenelzine regimen.

One of the major criticisms levelled at Dr. Sargent's treatments is that it is his forceful personality and not the drugs that is most effective. This, however, does not explain why the combination of "Gundy and phenelzine" is quite as successful as "Sargent and phenelzine"; nor does the personality factor explain why this improvement may start only 2–3 weeks after commencing the drug and not after the initial interview, and also if the drugs are discontinued it takes a week or so for the condition to return.

One case (treated solely by myself) which convinced me most was that of a man aged 49 who had been phobic since the age 13—that is, 36 years. He became completely symptom-free three weeks after taking phenelzine, and when his drugs were stopped for a blood-flow test his symptoms returned a week or so afterwards.

A very large number of cases seen since has confirmed my belief that phenelzine is a very effective drug for this condition, and in many hundreds of cases I have seen no serious side-effects, taking reasonable precautions.—I am, etc.,

G. H. GUNDY.

SIR,—The M.R.C. trial, like most trials conducted on the depressive illnesses seen in inpatients, showed the tricyclic antidepressants

to be superior to the monoamine-oxidase inhibitors. However, Dr. P. Leyburn and his colleagues (14 October, p. 108) imply that they are therefore of little value in the quite different types of depression seen in the outpatient departments of general hospitals.

In a recent review of over 10,000 patients subjected to clinical trials such a protagonist of the tricyclic antidepressants as Dr. I. F. Bennett¹ has confirmed that the monoamine-oxidase inhibitors are at least as effective as the tricyclic drugs in the outpatient type of case. This surely is added confirmation that there are at least two types of depression, and that some patients will only respond to the monoamine-oxidase inhibitors.^{2,3}

Like all potent drugs, the monoamine-oxidase inhibitors have side-effects and must therefore be used with caution, and only in patients whose disability warrants such risks. Even so, fatalities are rare, and with even the most "dangerous" drug, iproniazid, the mortality of 1 in 20,000 patients compares favourably with the 1 in 200 mortality accepted for the surgical treatment of, say, peptic ulcer.—I am, etc.,

Massive Overdose of Adrenaline

SIR,—While we agree with Dr. M. A. Lewis (7 October, p. 38) that the effect of very large doses of adrenaline must in part be open to speculation, we feel that what is known about the effect of smaller doses should be taken into consideration in the rational treatment of overdose.

In the first instance there appears to be no justification for the use of a ganglion-blocking drug. Arterial pressure normally depends to a considerable extent on the presence of vasoconstrictor tone mediated by sympathetic nerves, and interference with these nerves will cause a fall in arterial pressure in the normotensive subject. However, baroreceptor reflexes work in both directions, and when arterial pressure is increased there is reflex slowing of the heart and release of vasoconstrictor tone in an attempt to return arterial pressure to "normal." It is well known that such reflexes reduce to some extent the pressor effect of noradrenaline, and we have experimental evidence in man that the pressor response to small doses of adrenaline is potentiated by ganglion blockade.

We would suggest that the rational treatment of adrenaline overdosage must include the administration of a beta-receptor antagonist such as propranolol in addition to the alpha-receptor antagonist used by Dr. Lewis. This would control the cardiac stimulation caused by adrenaline and reduce the great risk of cardiac arrhythmia. The importance of both alpha- and beta-receptor antagonism has been recognized in the management of patients with phaeochromocytoma (another

of adrenaline overdosage), and this treatment and its rationale has been well described by Dr. E. J. Ross and his colleagues.¹

In cases of accidental overdosage we suggest the following treatment. Intravenous injection of phenoxybenzamine 20 mg. (to antagonize the vasoconstrictor action of adrenaline), followed by intravenous injection of propranolol 5 mg. (to antagonize cardiac stimulating effects of adrenaline). The propranolol should not be given first, as reduction of the vasodilator action of adrenaline may potentiate its vasoconstrictor action, resulting (in the absence of alpha-receptor blockade) in a further rise in arterial pressure. The subsequent dosage of phenoxybenzamine should be judged from the diastolic pressure, and of propranolol from the heart rate.

Dr. Lewis suggested that the hypotension following the episode may be explained when we have some information on the relative duration of action of alpha and beta effects. We have found that the beta (vasodilator) action of adrenaline in the human forearm is more persistent than the alpha (vasoconstrictor) action and that this prolonged vasodilator action can be abolished by beta-receptor blockade.² It is possible that a persistence of the peripheral vasodilator action of adrenaline may have contributed to the hypotension observed in this case.—We are, etc.,

National Kidney Centre

SIR,—I cannot allow some of the comments of Drs. M. H. F. Coigley and I. R. McWhinney (14 October, p. 112) to pass unchallenged. But firstly I must support them in acknowledging the indebtedness of all who practise intermittent haemodialysis to Dr. S. Shaldon, and particularly to his pioneering of home dialysis.

Your correspondents are, however, out of touch with the times when they infer that N.H.S. units are not home-orientated. Within 25 miles (40 km.) of their practice are two renal units within the N.H.S. with active home dialysis programmes, one of which (the Queen Elizabeth Hospital) had patients dialysing themselves at home before the National Kidney Centre opened. Without capable staff, thoroughly conversant with problems of dialysis and able to pass their knowledge on to others, one cannot teach patients self-dialysis. It has been the finding and training of such staff which has delayed most units from starting home dialysis. On a recent visit to North America I found nothing to support Dr. Coigley's suggestion that chronic dialysis programmes there are overall more orientated towards home dialysis than are those in Britain. Nephrologists on both sides of the Atlantic recognize Shaldon's and Dr. Scribner's achieve-

ments and appreciate that the logical extension of intermittent dialysis programmes is into the patients' homes.

Your correspondents, possibly because they are not directly involved in dialysis units themselves, underestimate the difficulties. I do not believe that any responsible renal physician would wish to conduct home dialysis without access to hospital facilities. In spite of your correspondents' claim, I can assure them that complications such as haemorrhage or septicaemia do occur on chronic dialysis programmes, even though they may be less common at home than in hospital dialysis. We have recently had occasion to witness the difficulties which may arise when responsibility for medical care is shared between a dialysis centre and another hospital centre. This is not an indictment of the remarkable achievements of the National Kidney Centre, but a recognition of the need for such a centre if it is to continue to have proper access to full hospital facilities. I am sure the Director would agree with this, and it is unfortunate that it has not been possible to make suitable arrangements to this end.—I am, etc.,

B. H. B. ROBINSON.

Cancer Chemotherapy

SIR,—Apart from experimental and pharmacological data very little is known about 5-fluoro-2-desoxyuridine (5-FudR). Indeed, the advantages of this preparation as compared with the concurrently used 5-fluorouracil (5-FU), which is much cheaper and has a similar spectrum of response in human tumours, seem still debatable,¹ and this has not encouraged the producers to give a large supply of the drug to clinical investigators. As we have had the chance to make some direct observations with 5-fluorouracil since 1961,² and with 5-FudR since 1964 (unpublished), it may be helpful to report briefly on our studies on 5-FudR.

Twenty-eight adult patients with various forms of disseminated cancer were admitted to the clinical trial of 5-FudR. They included 20 patients with mammary cancers; three patients with rectum or large-bowel cancer; one patient each with cancer of skin, tongue, pancreas, and prostate; and one patient with an adenocarcinoma with site of the primary unknown and multiple skin deposits. The administration schedule in 26 cases was: eight-hour venous drip of amounts varying between 50 and 100 mg. daily for 7 to 30 days (dissolved in 500 ml. of 5% dextrose). One case had an external carotid artery infusion, and one had an intrapleural injection.

Some degree of toxicity (mainly represented by gastralgia, vomiting, and diarrhoea) appeared in 11 of the 26 patients treated by the venous route. One of them had toxic manifestations after 10 days of treatment and all the others after more than 16 days. These side-effects reached important proportions in only six of the 11 cases (toxicity=2+ according to the Karnofsky criteria).³ In only one patient did we note frank leucopenia (1,500/cu. mm.). In nine cases leucopenia under 4,000 W.B.C./cu. mm. was found during treatment, but it must be pointed out that six of the patients showing leucopenia had begun the treatment with very low counts—namely, 2,200, 3,800, 3,100, 2,900, 3,800, 2,800/cu. mm.—and in none of these was a further drop of leucocytes noted during or after treatment. Platelet counts were not con-

sistently changed, and sometimes they increased. Only the haemoglobin content of the blood diminished almost constantly by 1 to 3 g./100 ml. This very mild damage to leucocytes and platelets is not common; our own experience does not suggest that treatment by 5-FU could have been given in such leucopenic patients.³

Clinical improvement began generally between the third and tenth days of treatment. There was an objective improvement in 12 cases and some subjective improvement in 20. Toxicity and clinical improvement were associated in only seven cases, while five objective and 13 subjective remissions were obtained without any toxicity. In some instances maintenance therapy by 5-FU on an ambulatory basis was possible after 5-FudR drip treatment, and it delayed the clinical relapse for months; otherwise relapse occurred between 15 and 45 days after stopping the treatment.

According to the described observations we suggest that 5-FudR be used instead of 5-fluorouracil by slow venous drip as a palliative anticancer drug for inducing remission in severely ill haematologically depleted patients (washed red cell transfusions being possibly added), and 5-FU be reserved for less ill patients or for maintenance therapy by weekly rapid venous injection of 10 mg./kg.²—We are, etc.,

Safer Dental Anaesthesia

SIR,—The Ministry of Health Report on Dental Anaesthesia¹ damns with faint praise the intravenous techniques which are used in dental surgery, and many will question the statement that, "Techniques such as that advocated by Jorgensen and associates . . . do not appear to be entirely satisfactory, particularly in children under 10 years of age, but seem to provide an alternative to general anaesthesia for conservative work in certain older patients."

There are many dentists who utilize this form of anaesthesia for their daily routine work, and, like Dr. Bourne,² I have been greatly impressed by the smooth manner in which dental surgical procedures may be carried out by incremental injections of intravenous anaesthetic, and the patient at the end of the operation is still able to walk from the chair with a little help. Certainly the dentist must be adequately trained in the anaesthetic technique, and have the assistance of two experienced dental nurses. The intravenous technique is further improved by using an intravenous drip of 5% dextrose as a medium through which intermittent injections may be given, and in this manner a session of extended rehabilitative oral treatment may be carried out in one session lasting for two hours or more. Safety is of course an important prerequisite to the use of any anaesthetic. In one series of 15,000 cases dealt with by the Jorgensen and intermittent

methohexitone methods³ no immediate or late complications occurred, and in 2,000 of these the treatment lasted for one to two and even more hours. The technique is described in a film.³

A Scottish dental school has recently proposed a diploma course in dental anaesthesia. While one must deplore the creation of too many "splinter" diplomas, the suggestion in this case is worth serious consideration, particularly if the course provides adequate training in the newer intravenous techniques.

Mental Handicap and the Family

SIR,—Your article, "Mental Handicap and the Family" (7 October, p. 5), gave a summary of the findings of a working party set up by the National Society for Mentally Handicapped Children. It may be of interest that a co-ordinating centre of the type described has been in existence in Glasgow for almost three years.

As a result of their investigation into the problems of the handicapped child and his family, begun in 1955, the Carnegie United Kingdom Trust made a grant of £30,000 to the Corporation of Glasgow to assist in setting up a centre at which services could be co-ordinated and parents could receive medical and social advice and support.¹ Glasgow Health and Welfare Department augmented this sum, and in December 1964 Balvicar Centre was opened. Since then 264 children have attended.

Pre-school children with all types of handicap are referred to the centre, which aims at providing all medical services other than in-hospital care. The centre is staffed by the health and welfare department, and consultants (paediatrician, orthopaedic surgeon, neurologist, ophthalmologist, otologist, child psychiatrist) are seconded from the regional hospital board to visit the centre at regular intervals. When inpatient treatment is required the consultant admits the patient to his own hospital unit. Routine hearing, vision, and psychological testing are carried out in all cases. A dentist, a psychologist, a physiotherapist, and a speech therapist also attend at the centre. An audiology unit functions within the centre. There is also a special day nursery, to which patients can be admitted for training. Play therapy groups are arranged for diagnostic and remedial purposes. Transport can be provided. General practitioners are kept fully informed of all diagnoses and treatment.

Parent guidance and support are most important. Advice on home management of patient, therapeutic apparatus, and suitable play material is given. Family planning and genetic counselling are available. Co-operation with hospital, social, and voluntary services is maintained, so that overburdened parents can be relieved by domiciliary help, housing improvement, and admission of patients for day or temporary residential care. Parents are encouraged to apply to the centre in family crises, so that prompt measures can

be taken to prevent breakdown. At intervals parents' meetings in the evening are held, with lectures, discussions, and films on relevant subjects. Continuity of care is achieved throughout the early years and the educational placing interview is conducted at the centre, where friendly and familiar surroundings reassure the parents and present the child at his best.

Even in this short space of time Balvicar Centre has proved once again the value of a multi-disciplinary team in dealing with handicapped children. The patients are assisted to reach their potential and the parents appreciate the co-ordination of advice and treatment at the centre.—I am, etc.,

Balvicar Centre,
Glasgow S.2.

REFERENCE

¹ Tizard, J., and Grad, J. C., *Handicapped Children and Their Families*, Reports to the Carnegie United Kingdom Trust on the Problems of 600 Handicapped Children and their Families, 1964. Dunfermline.

SIR,—In your leader "Mental Handicap and the Family" (7 October, p. 5) you quoted the recent report of the National Society for Mentally Handicapped Children,¹ which, although in many respects was admirable, gave an erroneous impression of the procedure of legal ascertainment. To say that this process is an administrative one designed for the negative purpose of excluding children from school rather than a positive attempt to decide what is best for the child's future is a misconception of what the medical staff of a good local authority are doing to provide community care for subnormal children.

In the vast majority of local authorities the same medical staff serve both the education and health departments, and the dichotomy referred to in the report is far less real than is implied. Most mentally handicapped children are known to the local health authority before school age, and at some stage a decision has to be made about whether his needs are best met by the regimen of a training centre or by the services of a special school. Most doctors working in this field regard this as a clinical matter, involving taking a history, making a physical examination, and psychometric or developmental assessment. Clearly children vary considerably, but only a limited number of establishments can exist for their training and education, so that they have to be placed in the establishment most likely to provide for their immediate needs.

Of course on occasions mistakes will be made and on other occasions the educational needs will alter, in which case they can be rectified, but the impression given that a once-and-for-all decision is made on one medical examination is far from accurate in most progressive local authorities today, and the decision about whether the child attends school or training centre is simply an incident in his continuing care, and one which allows considerable flexibility.—We are, etc.,

REFERENCE

¹ *Stress in Families with a Mentally Handicapped Child*, Report of a working party set up by the National Society for Handicapped Children, 1967. London.

SIR,—What Rip van Winkle was responsible for the leading article on the above subject (7 October, p. 5)?

Ten years ago, in accordance with the provisions of the National Health and Education Acts, Monmouthshire County Council, with the Welsh Hospital Board, had in operation a scheme for the mentally and/or physically handicapped child which, with the exception of income-tax relief, fulfilled each and every recommendation in this leading article. Moreover, some 10 years ago this scheme for the mentally handicapped child was fully reported in *The Medical Officer*,¹ a publication which would seem to have escaped your notice, but which brought visitors and correspondence from the other side of the world.

Finally, and again about 10 years ago, the members of the National Society for the Mentally Handicapped (then, I think, the Parents' Association) were told about this scheme at their own annual general meeting in London's Royal Festival Hall—told that local authorities have limited spending power, but exercise their own priorities, and advised that if they wanted a similar scheme in their own localities then they should take active steps to become elected members of their own local authority.

Truly, the prophet still has little honour in his own country.—I am, etc.,

Chronic Thyrotoxic Myopathy

SIR,—Dr. D. Gaan, in his interesting report of a case of chronic thyrotoxic myopathy with involvement of respiratory and bulbar muscles (12 August, p. 415), referred to doubts that have been expressed about the existence of acute "thyrotoxic myopathy" (affecting bulbar muscles) as a separate entity distinct from myasthenia gravis occurring fortuitously in a hyperthyroid patient. The case of a patient recently under my care does suggest that acute bulbar involvement may occur as the result of thyrotoxicosis alone; it is not conclusive, as he may have had acute myasthenia gravis with spontaneous remission, but this seems improbable.

The patient, a man of 73, was a proved case of thyrotoxicosis and had been treated medically for two years with apparent success. He was then lost sight of for a year, but had continued taking carbimazole in doses of from 5 to 15 mg. daily. He was referred again at the end of this time, having developed marked exophthalmos and ophthalmoplegia with diplopia, a goitre of considerable size, and typical pretibial myxoedema, none of which had been present when first seen. An edrophonium test was negative in that no appreciable improvements in ptosis or ocular movement was induced and on clinical and biochemical grounds (protein-bound iodine 4.8) he was regarded as euthyroid and suffering from typical "exophthalmic ophthalmoplegia." Carbimazole dosage was reduced to 10 mg. with a view eventually to discontinuance.

He remained well apart from the ocular condition for about three months, when he started losing weight and the P.B.I. rose to 8.1. He was complaining of general fatigue, though this was not of striking degree. Relapse of hyperthyroidism was suspected, but before treatment with radioactive iodine could be arranged he had

to be admitted to hospital as an emergency about six weeks later in a condition of extreme emaciation, his weight having dropped from eight stones (52 kg.) to under six stones (38 kg.). His voice was reduced to a feeble whisper, he could barely articulate, and was unable to swallow or cough effectively. Breathing was shallow and there were signs in the lungs compatible with inhalation of food material. There was generalized weakness of the body musculature, but not more than might have been expected in his cachectic state, and limb movements and reflexes were still present.

Iodine uptake and excretion 14 days before admission were in the "gross hyperthyroid" range and the P.B.I. was now 21.8. Urinary creatine (two estimations) was over 800 mg. per 24 hours and serum potassium lay between 2.4 and 3.1. A Gastrografin swallow, difficult to carry out, showed grossly delayed passage both at pharyngeal level and in the oesophagus. Tube feeding was attempted but proved impracticable, and the patient deteriorated rapidly, becoming semistuporous and looked like dying of inanition. Intravenous feeding was then started and later, despite a negative response to a second edrophonium test, a trial of neostigmine was made. From this time his condition changed for the better and swallowing and speech began to improve, though the response was by no means dramatic. In view of his high iodine uptake and excretion and serum P.B.I., carbimazole 60 mg. daily, as crushed tablets, was given throughout, at first by gastric tube, later orally.

Over a period of four or five days he improved to the point of being able to swallow fluid or semi-solid feeds, and neostigmine, discontinued at the end of this short period, was not required again. His subsequent gradual recovery was interrupted by severe neutropenia, thought possibly due to carbimazole, though he had been taking this drug for three years without apparent ill-effect. It was therefore stopped, with resultant partial relapse in thyrotoxicosis, and had to be reinstituted at a lower dose level, since it was believed that in this case it was literally a life-saving drug. With cortisone and transfusion the white count eventually reached normal levels and full recovery from the bulbar myopathy was achieved. He regained normal speech and swallowing and all his lost weight. When last seen, following radioiodine ablation of the thyroid and five months after the onset of the acute illness, he was well.

Neostigmine, given only for a few days, was not needed again; it is therefore difficult to regard this as a case of myasthenia gravis unless we assume that it underwent rapid spontaneous remission. If so, this occurred *pari passu* with successful control of thyrotoxicosis, which is not the sequence of events observed hitherto for true myasthenia gravis. Moreover, "limited relief of thyrotoxic myopathy with Prostigmin has been observed" and this cannot be used as a definite means of differentiation.¹ Just what part the brief period of Prostigmin therapy played in his recovery is difficult to assess, and the fact that recovery apparently began at that time may be fortuitous. It seems more likely that this case could be classed as acute thyrotoxic myopathy with the major onslaught on the bulbar muscles. There seems to have been an acute flare-up of hyperthyroidism in the few weeks prior to his emergency admission, the P.B.I. rising from 8.1 to 21.8 and the radioactive tests reaching high levels. This flare-up corresponded with the onset of bulbar paralysis. Ramsay² concludes that so-called acute thyrotoxic myopathy may simply represent one end of the spectrum of thyrotoxic muscle disorder.

The significance of the low serum potassium is uncertain; Whitfield and Hudson³ found normal potassium levels in their patients. They stressed the severity of the

hyperthyroidism in their cases, who were all "chronic," and also that men are predominantly affected.—I am, etc.,

W. M. PRIEST.

Corrosive Poisons

SIR,—I wish to comment on the statement on the treatment of corrosive damage to the stomach made by Drs. S. C. Kennedy and A. E. Bavaki (14 October, p. 93), where the use of magnesium bicarbonate was advocated.

Corrosive poisoning by acetic acid is not a rare occurrence in Ceylon, especially in the rubber-producing areas (acetic acid being used in the coagulation of rubber latex and being available "over the counter"). Our teachers used to impress upon us that magnesium hydroxide or dilute calcium hydroxide should be used locally in the mouth and be given orally whenever the patient could swallow—which was seldom. Bicarbonates were not advocated owing to the theoretically increased risk of perforation due to the evolution of gas, which I believe is a reasonable assumption.—I am, etc.,

London S.W.4.

D. R. MUNASINGHE.

Taking Blood Samples

SIR,—Following the letter from Dr. W. Joan Ferraby (7 October, p. 52), with which I agree, I have always been amazed why most doctors and technicians use a finger rather than the ear lobe, which I have found more suitable for the following reasons:

- (1) The skin of the lobe is cleaner—thus reducing the chance of sepsis.
- (2) The circulation is more easily stimulated.
- (3) There are fewer tactile corpuscles in the lobe and the skin is much thinner; hence the prick is less vicious and less painful.
- (4) Moreover, the apprehensive patient does not move nor witness the procedure, which is a great advantage.—I am, etc.,

London W.1.

I. MARTIN-SCOTT.

Prevention of Rh-haemolytic Disease

SIR,—Professor C. A. Clarke (7 October, p. 7) gives further results of the clinical trial on prevention of Rh-haemolytic disease with the use of anti-D gammaglobulin. He convinces that "prevention" is possible. It is realized that every detail in such a complex investigation cannot be reported, but it would greatly help those likely to be concerned in any future programme of prevention to have answers to some further points.

There are now reported 21 out of 131 treated women and 26 out of 136 controls who have had second Rh-positive ABO-compatible infants. The timing of antibody tests during and after this second pregnancy is not given, nor are facts about the infants. Have they all been Coombs' negative, normal, and liveborn?

Is it known of the remaining 110 women in the treated group that they have not been pregnant? How many have aborted during a second pregnancy, and have they also been tested for antibodies? How do these findings—for example, stillbirth or abortion rate—compare with the control group? Although in the treated and control groups the incidence of second pregnancies is similar, this seems small for the time interval. How does this rate compare with Liverpool as a whole?

In the *B.M.J.* (16 October 1966, p. 907) there was mentioned an experiment with anti-Kell, in progress, designed to find out if suppression of D-immunization was specific. Are these results yet available? One speculates, if suppression of D-immunization is able to suppress other blood group immunizations, whether there might not also be some impairment of general immunity to infection. Does this not require further investigation and close-controlled follow-up of treated women? A limited search for anti-gammaglobulin antibodies is mentioned and anti-Gm(a) has been found in 1 out of 20 treated women (5%). Does this represent the true incidence in so small a number? One might speculate that anti-gammaglobulin antibodies in some cases would have adverse effects if subsequent transfusion were necessary, that they might have clinical implications for subsequent infants if some of these antibodies could cross the placenta, or even have long-term effects for the patients themselves. There has already been one unexpected and as yet unexplained result of the experimental anti-D prevention work—that is, the IgM enhancement of immunization. What is the ultimate relationship of anti-Gm in rheumatoid arthritis likely to be? Gammaglobulin used for other indications—for example, rubella in pregnancy and hypogammaglobulinaemia—has not been blood-group specific, and this use might not be comparable to the use of anti-D γ in normal non-pregnant subjects.

These speculations all concern assessment of the risks to the treated patients. There is less doubt in weighing the risks of deliberate immunization to any Rh-negative volunteers. No one would wish the continuance of exchange transfusion, the family distress in Rh-haemolytic disease, and the possibility of stillbirth for any longer than necessary. But surely an intensification of research is called for to ensure as far as possible the long-term safety of treatment before it can be unquestionably right for national use.—I am, etc.,

Director, Region 1,
National Blood Transfusion Service,
Newcastle upon Tyne.

Salmonella in Tortoises

SIR,—I should like to draw the attention of your readers to the danger of tortoises as a cause of salmonella infection in children.

A patient of mine, a little girl aged 5, developed an attack of acute enteritis with abdominal pain, blood-stained faeces, and pyrexia. As there was no improvement following treatment, she was admitted to a fever hospital where *Salmonella typhimurium* was isolated from the stools. In the interim I discovered that the patient had a pet tortoise, which she frequently fondled, and so I suggested to the patient's mother that she should

have the faeces of the tortoise examined. This was subsequently done at the Royal Veterinary College, where *Salmonella canastota* was isolated from the faeces of the tortoise.

In order to establish the frequency of salmonella infection in tortoises I obtained the following information with the help of the Librarian of the Royal College of Veterinary Surgeons.

In 1958 Schwabe (unpublished) isolated 17 salmonella serotypes from 11 tortoises (*Testudo graeca*) imported from Morocco to Britain. In follow-up studies in Tangier 78% of tortoises examined were positive, and they yielded 15 salmonella serotypes from the terminal gut and rectum. In 1959 Bövre and Sandbu¹ isolated 19 serotypes, including two which were new, from 27 of 33 pet tortoises examined in Norway. All the strains were lethal to mice. In 1962 Boycott² reported isolation of salmonella in England from 41 of 45 *Testudo graeca* and 33 of 50 wild tortoises examined. The increasing hazard to public health was emphasized by some statistics published in 1961 by the Universities Federation for Animal Welfare,³ in which they stated that in a few years prior to 1961 46 tons of pets from Morocco were imported to Great Britain, whereas by 1961 this figure had reached 80 tons per annum.

I should therefore like to emphasize that in any unexplained salmonella infection, especially in a child, careful inquiries should be made about the possibility of a pet being the vector of the infection.—I am, etc.,

Abortion and Conscience

SIR,—The Abortion Act has now passed its final stage and is law. Because of the determination of the sponsors to have the law changed before there was a full inquiry into the facts there is still no body of reliable evidence to guide doctors or the public in the interpretation of the various clauses.

One point seems clear, and that is the new law will permit a doctor to refuse to recommend or perform an abortion on grounds of conscience. This clause was intended to protect those doctors (and nurses) with strong religious objections to abortion. There are, however, conscientious objections other than religious. There is a medical conscience which dictates that one should not interrupt the process of human life unless there is good evidence that such a measure is entirely justified in order to avert a dangerous situation. This used to mean one which was dangerous to the mother, though now we must consider danger to other members of the family and no doubt eventually to society.

A doctor's conscience should be satisfied that these dangers are real, adequately proved, and fully relevant to the patient's situation. If this evidence is not forthcoming a doctor's conscience would prevent him from taking such drastic action. That the law makes it permissive for doctors who have not got this medical conscience does not remove

from the doctor who possesses one the right to act according to it. It would be intolerable for a doctor to be pressurized into what he considers to be bad medical practice in order to conform with a new law. Parliament may well have thought that the number of "cranks" who will not abort without adequate medical indications are few and can be ignored. I question this. It has been possible for a "permissive" gynaecologist with the support of "permissive" psychiatrists to earn legally £250,000 in one year. This alone indicates that most gynaecologists, who are presumably no less competent, are not tripping over themselves to enter

this lucrative field. Their medical conscience is more important to them than wealth.

One does not wish at this stage to raise objections to a new law, but it is important to declare that a medical conscience should not require a special dispensation but is our main *raison d'être* as a profession. We must not only protect it, but try to convert our lapsed colleagues with the medical evidence. I now feel that I, too, can campaign for Abortion Law reform, but this campaign will be based on existing facts and a continuing search for truth.—I am, etc.,

Edgbaston,
Birmingham.

MYRE SIM.

Fluoridation of Water Supplies

SIR,—Dr. Ronald L. Kerr is entitled to his personal views regarding the fluoridation of water supplies (21 October, p. 176), but he must surely be aware that the evidence he has adduced in favour of his arguments has been systematically and patiently refuted during the last 10 years.

The refutations have been stated so frequently and at such length, indeed, that I would not presume to ask for further space in your correspondence columns to deal with them. Perhaps the handiest compendium of information, which includes the arguments of anti-fluoridationists, is the report of the proceedings of the Eire High Court, following which Mr. Justice Kenny delivered his now famous judgement.¹

All who have made a special study of fluoridation have included the study of the case against the measure, and, although there may be a handful of people who have doubts, the practical experience of the effectiveness and safety of this measure, supported by a mass of fundamental research, has dispelled the slightest doubt from the minds of the majority. At no time during the period in which fluoridation of water supplies has been practised in any country of the world has a single case come to light of illness caused by, or aggravated by, the consumption of water containing one part per million of fluoride.—I am, etc.,

A. J. DALZELL-WARD,

Medical Director,
Central Council for Health Education.
London W.C.1.

REFERENCE

- ¹ *Fluoridation*, judgement delivered in the High Court by Mr. Justice Kenny, Dublin, 1963 (Department of Health, Dublin).

SIR,—I was impressed by Dr. Ronald L. Kerr's letter (21 October, p. 176) with its comprehensive references, and would like to emphasize one of the points he raised.

If we allow the public water supply to be used as a means of mass medication in order to influence a small section of the community (at the same time ignoring its effect on the much greater remainder) it introduces a most dangerous precedent of dictatorship, against which tyranny this country has fought on many occasions in the past.

We may next be forced to accept somebody's whim of putting oestrogens in our drinking-water in the hope of preventing prostatic cancer in a limited number of elderly men, while ignoring its effect on the women of the country.

Surely it is time the B.M.A. had the courage to admit it has made a mistake in supporting such a blindly unscientific and dangerous policy.—I am, etc.,

East Grinstead,
Sussex.

H. TUDOR EDMUNDS.

SIR,—To Dr. Ronald L. Kerr's letter on this subject (21 October, p. 176) I would like to add a postscript, if I may, to the effect that before such a project is put into practice it is the duty of its proponents to establish their case for it doing some good, which, in my submission, they have not done. Nothing in the way of convincing evidence has so far been put forward and the "pro" case appears to rest entirely on suitably selected statistics about "60% reduction of dental caries" (whatever that means). Statistics can be made to "prove" that black is white.

The classical "control experiment" case of North and South Shields, where South Shields had water with a naturally occurring fluoride content of 1 p.p.m.—the optimum advocated by the proponents—while North Shields had none, was reviewed by the Government's own spokesman Dr. R. Weaver,¹ who showed grounds for supposing, as Dr. Kerr quotes, that dental decay in South Shields was postponed for two to three years without its total amount being affected. But there has been no hint of a reduction in the cost of dental services, or any increase in the level of general health in the latter town.

Less publicity is given to the authoritative work *Fluorine Intoxication*, by Dr. Kaj Roholm,² which is available in the British Museum library. He gives a most emphatic and unqualified warning that in no circumstances whatever should children be given fluorides in any dosage whatever.—I am, etc.,

Liskeard,
Cornwall.

W. H. SPOOR.

REFERENCES

- ¹ Weaver, R., *Proc. roy. Soc. Med.*, 1948, 41, 284.
- ² Roholm, K., *Fluorine Intoxication*, 1937. Copenhagen.

SIR,—I was most interested to read Dr. Ronald L. Kerr's most excellent letter on the subject of fluoridation of drinking-water (21 October, p. 176).

May I say how much I endorse every word of what he says. Any member of the community is free to take fluoride if he wishes to do so. Can there be any sense in denying

him the right to refuse to take it if he so wishes?—I am, etc.,

Fulmer, Bucks.

RICHARD FAGAN.

SIR,—I was pleased to see the letter on this subject by Dr. Ronald L. Kerr (21 October, p. 176), who takes up the only reasonable approach to this subject. It was a great tragedy when the B.M.A. accepted the recommendation of a subcommittee to encourage fluoridation and so erode still further what little freedom we have left. Both freedom and health are lost under fluoridation.—I am, etc.,

Glasgow.

W. HAROLD EMSLIE.

SIR,—Dr. Ronald L. Kerr's letter (21 October, p. 176) seems unanswerable on medical or ethical grounds. If fluoride against caries, why not other toxic "preventive medication" that any strong lobby might persuade the authorities to add to the water? These things always begin as the wholly beneficent intention of men who know what is good for the people.

I am not given to supporting campaigns, but I must in this important test case add my voice to protest against a piece of political arbitrariness which goes far beyond the civically or scientifically justifiable.—I am, etc.,

London W.1.

H. V. DICKS.

SIR,—The plea by Dr. Ronald L. Kerr (21 October, p. 176) for a reassessment of the question of fluoridating the water supplies is timely, and should be seriously considered by the B.M.A. Council and the Ministry of Health.

To my mind the most important aspect of all is the ethical one. It seems strange that the Ministry of Health can promote—and the B.M.A. support—a line of conduct which if practised by an individual would not be tolerated either by the public or by the Ministry itself. If a doctor gave his patients treatment against their wishes he would render himself liable to an action at law for assault. A plea that he believed the treatment to be beneficial might mitigate sentence but would not clear him of the charge. If it transpired that he knew that some of his patients so treated could not possibly benefit from it his only hope would be to plead guilty but insane.

Apart from the criminal aspect, such an offender would probably find himself in serious trouble with the G.M.C., and, should the victims be N.H.S. patients, he would risk severe penalties from the Ministry of Health acting through the local executive council.

Why can the Ministry of Health and the B.M.A. get away with it?—I am, etc.,

Brighton, Sussex.

G. R. MITCHELL.

SIR,—Surely Dr. Ronald L. Kerr (21 October, p. 176) cannot be serious in his suggestion that fluoridation is "compulsory mass medication." Every piped water supply contains some natural fluoride, in some areas at a higher concentration than one part per million. Fluoridation, which in temperate zones means the adjustment of F ions in the water to 1 p.p.m., has been achieved in some areas merely by mixing natural waters of

differing fluoride content. Can this be called "mass medication"? The fact that in this country fluoridation would usually involve the addition of F ions is immaterial to this argument. In some parts of the world, such as large areas of the Sudan,¹ a reduction in the fluoride content of well-water would be needed to produce the optimum concentration.

Fluoridation in the U.S.A. was started over 20 years ago and now is supplied to more than half the population receiving piped water. Vigilant public health authorities have confirmed that the only effects are dramatic reductions of dental decay, together with some still not fully substantiated reports of reduction in the incidence of osteoporosis of the aged.—I am, etc.,

R. D. EMSLIE,

Chairman, Dental Health Committee,
British Dental Association.

Adams-Stokes Syndrome

SIR,—Congratulations to the B.M.J. for encouraging (28 October, p. 199) the use of the old-fashioned but truer name for the syncopal syndrome associated with complete atrio-ventricular block—the "Adams-Stokes Syndrome"—in preference to the now frequently used "Stokes-Adams Syndrome." The latter has been too widely adopted for the usual slovenly modern reason that it comes more easily to the tongue than the former, and so tends to be used in spoken bedside or lecture-room teaching. There can be little doubt about the primacy of Adams, who wrote in 1827, over Stokes, whose cases were described in 1846. It ought not to be overlooked that the first cases were described by Morgagni in 1762 and Spens in 1793, but perhaps the "Morgagni-Spens-Adams-Stokes Syndrome" would be in danger of becoming slurred into the "Stokes-Adams Syndrome."—I am, etc.,

Edinburgh.

J. G. M. HAMILTON.

Use of Thorotrast

SIR,—I have read the letter from Dr. G. A. Granger (14 October, p. 112) with some interest. Dr. Granger implies in his letter that the recent article by myself and Dr. E. R. D. Williamson (22 July, p. 206) indicates that Thorotrast may be used for conditions other than those specified by the U.S. Food, Drug, and Cosmetics Act, details of which are given in the literature enclosed with each vial of Thorotrast sold in the U.S.A.

I would like to point out that our article referred to the former use of Thorotrast in Britain, and that the study on which it was based was specifically undertaken, as was pointed out in the paper, to obtain information on the morbidity which may follow the use of this substance. With one exception the cases which we studied were given Thorotrast prior to 1947. As far as I am aware the clinical use of Thorotrast was discontinued in Britain at that time because of an increasing awareness of the dangers inherent in the use of a radioactive substance

which is retained indefinitely by the body. Such dangers are illustrated by reports of very extensive chromosome damage found in patients who have received intra-arterial injections of Thorotrast.^{1 2}—I am, etc.,

Oculogyric Crises after Phenothiazines

SIR,—The neurological complications associated with the use of perphenazine are "as yet poorly recognized," according to Drs. E. C. B. S. Keat and P. J. Toghill (30 September, p. 867). If this be the case it is my contention that the manufacturer cannot be blamed.

In 1964 a 26-year-old patient in the second trimester of her second pregnancy was given Fentazin Duolets (6 mg. perphenazine in a long-acting tablet). She had taken one tablet 12-hourly for but three days when I received a message suggesting that the patient had "lock-jaw." The patient's husband had good perception. The risus sardonius with which my patient greeted me was quite startling. Thanks to the manufacturer's information leaflet I was not side-tracked into a bizarre diagnosis. It may be argued that I was fortunate in having this information ready to hand in my "series" of one.

To plead ignorance when information has been disseminated (and indeed continues to be thus included in each original pack of tablets of the drug in question) does not seem justifiable to me.—I am, etc.,

WILLIAM J. O'CONNELL.

Fareham, Hants.

Consultant Distinction Awards

SIR,—The results of the B.M.A. ballot (*Supplement*, 21 October, p. 22) revealed very little of the opinions of consultants on distinction awards, as the questions asked were so few. They did show, however, an overwhelming majority in favour of change, and this must indicate widespread dissatisfaction. It is to be hoped that this dissatisfaction will be resolved in public and private debate. Clearly the majority favour awards as a means of acknowledging those who have made outstanding contributions to medicine, but the scheme loses its point when a very large proportion of consultants are given awards. One-third at present receive them, and in the course of a career more than a third, possibly more than a half, might receive an award at some time or other. This has three serious disadvantages.

Firstly, the further down the rank-and-file of consultants the distinction awards extend the more difficult it becomes to decide who shall get them and who not, and this is a great source of unrest. It is widely felt that the criteria on which the "C" awards are made are very slender, and if the rule of secrecy were lifted many decisions would be very difficult to defend. This is no slight

on responsible committees, but an indication of the difficulty of their task and the small amount of information they work on.

Secondly, as distinction awards are so widely attained, any committee considering consultants' salaries is bound to consider awards as part of the salary structure, to the detriment of those who do not have them.

Thirdly, by awarding a label of merit to one-third of consultants there is an immediate implication that the remainder are without merit, which puts them at an immediate disadvantage in salary negotiations. As a result there are numerous consultants who have done 10 years' postgraduate training and acquired two or three higher qualifications who earn much less than many of their general-practitioner colleagues.

The solution to this unsatisfactory pay structure is to reduce the number of merit awards and confine them to doctors of undoubted merit. The "C" award should be abolished and incorporated in the normal pay structure. Whatever happens, our negotiators must establish a proper salary structure for specialists independently of the merit awards, otherwise the non-merit-award consultants will rapidly become the Cinderellas of the Health Service.—I am, etc.,

Ashington Hospital,
Northumberland.

T. MANNERS.

Approval of Emergency Treatment Service

SIR,—The reason for the B.M.A.-sponsored Emergency Treatment Service not getting off the ground has, I submit, little to do with delay in obtaining approval (21 October, p. 176). It lies elsewhere.

Firstly, the insistence that membership of the Emergency Treatment Service shall be confined to subscribers to the Telephone Answering Service. This proviso operates to the detriment of those of us who go to great trouble to maintain standards by ensuring that our telephones are always manned, and who therefore have no need of a telephone answering service. Our reward is to be barred from membership of a B.M.A.-sponsored Emergency Treatment Service. I am impelled to ask what sort of general practice the B.M.A. is seeking to encourage. Is it the second-rate lock-up, or one where the practitioner seeks to ensure that telephone calls are properly dealt with and not left to the caprice of an inefficient G.P.O. telephone transfer service?

Is the Emergency Treatment Service not familiar with the situation where a caller hangs up in despair long before the transfer service cuts in? That is why some of us do not wish to depend on an answering service. I am not unaware of the commercial element in all this, whereby the firm running the telephone answering service looks to the income therefrom in order to provide a cushion against loss in running an emergency treatment service. This does not make the proviso any more palatable. The Central Advisory Committee should do more than pay lip service to the best standards of practice organization, and they might make a start by scrapping the requirement of Telephone Answering Service subscription.

Secondly, the Emergency Treatment Service is quite simply too expensive. Complaint to this effect is met by the organizers pointing out that the subscription is intended to cover 25

calls per month, but, Sir, apart from a few areas, this figure greatly exceeds actual numbers in the experience of most of us. I have a not inconsiderable list and my average is seven emergency calls a month, which on the Emergency Treatment Service scale would work out at £3 a call. The night call refund from executive councils makes little impact, since most night calls originate before midnight; and may I further remind the Central Advisory Committee that executive councils via the Minister have set their faces against handing over all night and weekend calls to a call service, and suggest that those wishing to do so should instead opt out of night work altogether and forgo the payment therefor. (It is in fact only by handing over all out-of-hours calls to a service that 25 visits would accumulate even in bad areas.) Further it should not be necessary for me to remind the sponsors that the use of call services is rationed by appropriate committees to so many calls per thousand patients per year as a condition of approval of use, and that it would be only enormous lists which would approach a ration of 25 calls per month. No single-handed doctor could possibly approach it.

No, Sir. The organizers must adopt a much more realistic attitude towards a viable Emergency Treatment Service.—I am, etc.,

M. MUNDY.

London W.8.

SIR,—Dr. W. P. Lambie's castigation of the Inner London Executive Council over the B.M.A.'s Emergency Treatment Service (21 October, p. 176) is as unfair as it is unwarranted. While deploring any undue interference by an executive council into a general practitioner's affairs, they do have the statutory duty of ensuring that patients are properly cared for. After the necessity of a ministerial inquiry into the workings of the B.M.A.'s Glasgow E.T.S. any executive council would proceed cautiously.

However Dr. Lambie might protest, it does not explain why the B.M.A.'s E.T.S. repeatedly stated that it would not open up in any area where there was already a satisfactory service unless the E.T.S. was sufficiently demanded; repeatedly claimed that its service was sufficiently demanded in those areas; repeatedly has its claim refuted in practice, there following disgruntled withdrawal.

In the words of the song "When will they ever learn?"—I am, etc.,

B. JOHN MAXWELL,
Medical Director,
Liverpool Locums Limited.

Liverpool 6.

Foreign Residents

SIR,—A retired American citizen applied to be on my list. I made him a temporary resident, and then inquired from my executive council what the position was regarding his entitlement to medical services. I was informed by the executive council that an American citizen now permanently resident in England is entitled to apply for acceptance as a National Health Service patient.

Are we going to accept all retired people from foreign lands who have never contributed a penny? Isn't this socialism gone

mad? There is no quid pro quo in foreign lands. Are we to look forward to an England which is to be a dumping ground for old or retired persons as well as foreign goods? By 1980 this island might well be a home for cripples and geriatrics.—I am, etc.,

London S.W.5.

O. S. THOMPSON.

Was it a Drug?

SIR,—Did my eyes deceive me? I read in the *Supplement* (9 September, p. 128), "The Minister's representative . . . maintained that the mother was responsible for the inflammation, and that she should have paid for the remedy. . . ."

This is another example of bureaucracy gone mad, and must lead the profession to fight even harder than ever before for the right to prescribe what they consider to be necessary on clinical grounds without for ever looking over their shoulders in fear of being charged for treatment given to their patients.

We are a responsible body of professionals and act on behalf of our patients with good faith. This should be made clear to the Ministry, and the offending regulations should be withdrawn.—I am, etc.,

Seven Kings,
Essex.

I. M. SEGAL.

Points from Letters

Respiratory Distress Syndrome

Dr. FRANK MARSH (Epping, Essex) writes: You state that the paramount importance of the accurately controlled administration of oxygen cannot be overstressed (9 September, p. 628). I would like to suggest the administration of humidified oxygen through a ureteric catheter made of radio-opaque material, and passed through the larynx (locally anaesthetized) until the tip is at the bifurcation of the trachea, to overcome the "dead space." . . . The catheter under certain conditions might be passed through a tracheostomy opening.

Self-expulsion of a Nasal Polyp

Mr. A. HEDLEY BROWN (London S.E.1) writes: Recent evidence (5 August, p. 372, and 19 August, p. 500) shows that nasal polypi can be expressed by the patient.

My mother, before visiting an E.N.T. specialist after a lifetime of recurrent sinusitis, had a worse attack than usual. Sniffing despairingly, she produced a pedunculated polyp the size of an acorn into her mouth, with the cure of her symptoms. The specialist did not believe her, though she was a nurse, for she had not preserved the specimen. Perhaps he will now.

Computer Miscontrol

Dr. L. C. PAYNE, Ph.D. (Shenley, Herts) writes: A letter in the *B.M.J.* under the heading of "Computer Control" (23 September, p. 802) refers to "bureaucratic dominance by computer" in which the Ministry of Social Security (according to your correspondent) would not permit a valid exception to some administrative procedure because "it would interfere with the computer programme."

This is utter nonsense. The computer is a machine which simply performs a sequence of operations specified to it by a programme, as does an automatic washing machine. . . . What your correspondent is describing, therefore, is not computer control but bureaucratic inflexibility.

Obituary Notices

H. G. GARLAND, T.D., M.D., F.R.C.P.

Dr. H. G. Garland, consultant physician in charge of the neurological department in the General Infirmary at Leeds, died at his home on 23 October. He was 64.

Hugh Gregory Garland was born in Bridlington on 8 October 1903. After receiving his early education locally he entered Leeds University Medical School, graduating M.B.,

Ch.B. with distinction in 1926 and taking the Conjoint diploma the same year. After holding resident appointments in the Leeds Infirmary he was appointed a resident at the National Hospital for Nervous Diseases, Queen Square, and later at the Brompton Hospital. On his return to Leeds,

after holding further hospital junior appointments, he became medical tutor in the Leeds Infirmary, achieving a reputation as a first-class clinical instructor. He took the M.R.C.P. in 1929, and in the following year proceeded M.D. with distinction. In 1934 he was appointed honorary physician to the Leeds Public Dispensary, where for the next three years he was associated with Professor S. J. Hartfall in the gold treatment of rheumatoid arthritis. In 1937 he was appointed honorary assistant physician to the Leeds General Infirmary. By this time he had already entered private practice, and had become well known as a neurologist. He was elected F.R.C.P. in 1939. As a territorial officer he served in the R.A.M.C. throughout the whole of the second world war. After a short spell as a battalion medical officer at the beginning of the war, he was posted to Davydhulme Military Hospital as a medical specialist. He later served in a similar capacity at the Queen Alexandra Military Hospital, Millbank, until his posting to York Military Hospital as Northern Command neurologist in 1941. In November 1943 he went out to India to become adviser in neurology to the Southern Army with the rank of lieutenant-colonel. He held this appointment until his demobilization in November 1945. During his period of service in this capacity he travelled extensively and had charge of a large neurological centre in a base hospital. After the war he returned to his post at the Leeds General Infirmary. In 1946 he founded, and became physician in charge of, the neurological department, an appointment which he held until his death. In 1948 he became senior clinical lecturer in neurology in the University of Leeds, and at the inception of the National Health Service in 1948 he also became consultant neurologist to the Leeds Regional Hospital Board.

During the course of his professional career Hugh Garland held many important

appointments. At various times he was president of the Leeds and West Riding Medico-Chirurgical Society, the neurological section of the Royal Society of Medicine, the North of England Neurological Association, and the Leeds and West Riding Medico-Legal Association. He was, in fact, a founder member and the first president of the two latter associations. He was also a founder member of the Association of British Neurologists, and a councillor during the years 1947 to 1951. A member of the British Medical Association, he was vice-president of the section of neurology at the Annual Meeting in 1950, and president in 1957.

Hugh Garland was a man of exceptional ability, embellished by a complex and colourful personality. He was an outstanding teacher, and was greatly in demand as a lecturer and speaker. In addition, he was a prolific and lucid writer, publishing over a hundred papers on a wide variety of subjects in many different journals. He was the senior editor of a textbook of medicine which was published in the early 1950s, had many novel features, and was extremely well received.

During the years 1949 to 1955 he was editor of the *Leeds University Medical Journal*. Some years later he organized a series of lectures on the scientific aspects of neurology in which a number of eminent visiting speakers took part. The lectures were subsequently published in book form. His quick grasp of essentials and his fluency of expression made him a much-sought-after administrator, as well as contributing to his success in medico-legal practice. He had an exceptionally long tenure of office as chairman of the Faculty in the Leeds Infirmary, and also served on the Board of Governors for many years. Latterly, he also became chairman of the medical advisory research committee of the Multiple Sclerosis Society of Great Britain and Northern Ireland. Although virtually his entire professional life was devoted to the service of his teaching hospital, he also acquired a world-wide reputation as a neurologist, and became well known as the leader of a tetanus treatment team. He was intensely loyal to all those whose future depended upon his patronage, and there are many who owe much to his guidance, support, and encouragement during their early formative years. Fond of good company, his reputation as a *bon viveur* was proverbial. A keen sense of humour and a ready wit enlivened his many activities. Never daunted by authority, he loved to demolish long-cherished beliefs, especially if they had flimsy foundations. Prone at times to display autocratic and dogmatic attitudes, he would delight in generalizations which sometimes seemed outrageous, yet even his sternest critics had to concede the truth which they so frequently contained. He had prodigious energy and resilience; his alertness of mind was perhaps his greatest asset, and there seemed to be no place in his life for either inactivity or infirmity.

He is survived by his wife and a married daughter.—M. J. P.

J. P. writes: The passing of Hugh Garland has left an unbreachable gap, both in British neurology and in the Leeds General Infirmary. He was an outstanding teacher, and certainly the best lecturer that Leeds students were privileged to attend. His precision and clarity of thought and expression made him a most stimulating and exacting chief to work for. He did not suffer fools gladly, and was sometimes intolerant of those less gifted than himself. As a clinical diagnostician he was superb. With logical thought, scrupulous accuracy, and above all a flair of diagnostic inspiration, he was seldom wrong. He was never too proud to say, "I don't know," but at such times neither did anyone else. His flamboyant and endearing personality was felt beyond the confines of medicine, but he was happiest with a crowd of old associates around him retelling, in extraordinary detail, tales of earlier days. With his staff he was exceedingly generous, and was always at great pains to further their careers, a task in which he never failed. His academic achievements are legion, but he was especially proud to be the president of the neurological section of the Royal Society of Medicine, and to be the founder, father, and first president of the North of England Neurological Association—which he aptly christened N.E.N.A. A prolific writer, he made many outstanding contributions to clinical neurology; his papers on hypertrophic polyneuritis, endogenous hypoglycaemia, and diabetic amyotrophy are classical works of reference. In administration he was outstandingly successful, and was in constant demand as a chairman of numerous hospital committees as well as being the chairman of the research committee of the Multiple Sclerosis Society of Great Britain. In everything he laid his hands to, Hugh Garland showed himself to be a man of great intellectual powers, moral courage, and integrity.

P. T. HERRING, LL.D., M.D.
F.R.C.P.ED., F.R.S.ED.

Emeritus Professor T. P. Herring, of St. Andrews University, died on 24 October at his home at St. Andrews. He was 94. The death of Percy Herring has meant the loss of one of the distinguished physiologists who emanated from the illustrious and world-famous school of physiology which flourished under the guidance of the late Sir Edward Sharpey-Schafer.

Percy Theodore Herring was born in Yorkshire on 3 November 1872, but at an early age he emigrated with his parents to New Zealand, and it was while he was there that he received his school education in Christchurch and then proceeded to Otago University. Like many New Zealanders, in the latter part of the last century he came to Edinburgh to continue his course in medicine, and it was during this time that he

established the pattern of the academic brilliance which was to be a feature of his future work. He graduated M.B. in Edinburgh with first-class honours in 1896, after which he held resident posts in Edinburgh Royal Infirmary and at the Simpson Memorial Hospital. In 1897 he was awarded the Murchison Memorial Scholarship in clinical medicine, and one year later received the Crichton Research Scholarship in pathology. While

holding this scholarship he pursued investigations which led in 1899 to his being honoured with a gold medal for his M.D. thesis on "A Study of the Malpighian Bodies of the Kidneys." He took the M.R.C.P.Ed. in the same year. While in the pathology department he formed a close and lasting

friendship with the late Sir Robert Muir, and he frequently made reference to the stimulus and deep personal pleasure that he had obtained from this association with him. He was elected F.R.C.P.Ed. in 1903.

When Edward Sharpey-Schafer was appointed to the chair of physiology in Edinburgh in 1899, Herring joined his research staff as the holder of the Goodsir Memorial Fellowship in anatomy and physiology. During his early years with Schafer he became engaged on a histological study of the pituitary gland, and especially in regard to its posterior lobe. It was then that he described the granules in the neurohypophysis which are now customarily designated "Herring bodies," and whose functional significance has provoked so much investigative work; Schafer fully recognized the importance of Herring's work in the volume of *Quain's Anatomy* devoted to microscopic anatomy. He subsequently joined the staff of the physiology department, and it was during the first decade of this century that through his outstanding ability as a teacher he made such a stimulating impact on preclinical students in Edinburgh. Herring was a man of outstanding personality, and was punctilious in all he undertook. It was in keeping with

these attributes that he had been elected president of the Royal Medical Society in 1898, and it was likewise in keeping with his academic achievements that he was elected to the Chandos chair of physiology in the University of St. Andrews in 1908. This position he held until his retirement in 1948, and during his tenure of office he was Dean of the Faculty of Science from 1921 until 1939. St. Andrews University recognized its gratitude to him for all he had done for it by conferring upon him the degree of LL.D. He took a major part in the affairs of St. Leonard's and St. Katherine's School, of whose council he was chairman from 1930 to 1947, and it was due to his judicious and far-sighted policy in many matters that the school continues to prosper. A member of the British Medical Association, in 1910 he was vice-president of the section of physiology at the Annual Meeting, and in 1927

vice-president of the section of physiology and biochemistry.

Professor Herring was a pleasant and stimulating colleague who had a charm of manner and a warmth of personality which will never be forgotten by those who knew him. He celebrated his diamond wedding two years ago, and is survived by his wife and four daughters, three of whom are medical graduates of St. Andrews University.—R. W.

J. C. DICK, M.D., F.R.C.P.GLASG. F.C.PATH.

Dr. J. C. Dick, senior consultant pathologist to Glasgow Northern Hospitals, died on 21 October at the age of 56.

John Carson Dick, the son of a Glasgow schoolmaster, was born in Glasgow on 28 March 1911, and was educated at Hutchesons' Boys' Grammar School and at Glasgow University, where he graduated M.B., Ch.B. in 1933. He became interested in pathology, and joined the staff of the Glasgow Royal Infirmary under the late Professor Shaw Dunn. While there he proceeded M.D. in 1938, and was awarded honours and the Bellahouston gold medal for his thesis "Elastic Tissue of the Skin." During the second world war he served in the R.A.M.C. as a specialist pathologist with the rank of major, and was posted to the Canal Zone. Among his other duties he carried out research and original work on typhus and the Weil-Felix reaction. He was mentioned in dispatches. After demobilization he returned to the Glasgow Royal Infirmary, but on 1 July 1948 he was appointed senior pathologist to Glasgow Corporation Hospitals, and headed his department in Stobhill General Hospital. Later he was appointed senior lecturer in pathology to the University of Glasgow. In 1952 he was elected Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow, and in 1962 was admitted as a Fellow of the Royal College of Physicians of Glasgow. The following year he became a founder Fellow of the College of Pathology.

Dr. Dick contributed to many scientific journals, and was recognized as an international authority on the effects of drugs in the treatment of tuberculosis, particularly as it affected the urinary system. This original work he started in 1948, and by 1955 he had published many articles on the effects of streptomycin, P.A.S., and isoniazid on renal tuberculosis. Until his death he still maintained his interest in this subject, and his earlier findings still retain an important place in medical literature. He was a very skilful pathologist, a fine colleague and friend with whom it was a privilege to have been associated.

He leaves a widow, two sons, and a daughter, to whom the many friends of Dr. Dick extend their deep sympathy.—W. M. B.

R. R. W. writes: I did not join John Dick's staff until 1964, when he was already suffering from the illness which ended in his untimely death. It is not for me to speak about him as a pathologist, but I can and must show my respect for the man. Almost the first thing I learnt was that all

his staff thought well of him and were fond of him. I never heard an unkind word said of him, nor heard one from him either. He endured his ill-health with a combination of objectivity and quietness that would be hard to emulate. So it was that all his staff, medical and non-medical, did what they could to help him, as occasion indicated, out of their admiration, their affection, and their compassion. And now in corresponding degree our sympathy is offered to his family.

W. NAPIER, M.D.

Dr. W. Napier, consultant physician to the Paisley and Renfrewshire Infectious Diseases Hospitals until his retirement in 1961, died in Mearns Kirk Hospital on 8 October after a long illness borne with exemplary patience and fortitude. He was 71.

William Napier was born on 30 January 1896, and was educated at Ayr Academy and Glasgow University, where he graduated M.B., Ch.B. in 1918. During his university career he won the Asher-Asher gold medal among other prizes. After graduating he served in the R.A.M.C. in Mesopotamia for two years, and attained the rank of captain. After demobilization he held several junior posts in the Glasgow Western Infirmary, the Glasgow Royal Maternity Hospital, and Belvidere Fever Hospital, Glasgow. In 1923 he was appointed deputy superintendent of Belvidere Fever Hospital, and in 1925 he became superintendent of Shieldhall Fever Hospital, a post which he held until 1952, when he was appointed consultant physician to the Paisley and Renfrewshire Infectious Diseases Hospitals. A thesis on "Puerperal Fever—A Review of 500 Cases" gained for him an M.D. with commendation at Glasgow University in 1928. While his work covered every aspect of infectious diseases he was especially interested in diphtheria, and contributed a paper in 1937 advocating early tracheotomy in laryngeal diphtheria. Among other papers he published was one on "Febrile Reactions Among Smallpox Contacts" as the result of a study of smallpox contacts during the 1942 outbreak in Glasgow.

He was a man of a quiet, gentle disposition and simple tastes, with a great love of family life, classical music, and literature. He was fond of the open air and was never happier than when tramping over the moors of Renfrewshire and his native Ayrshire with his family. He was also a keen member of the Church of Scotland, and was an active supporter of his church, being an elder for 28 years.

In 1934 he married Miss Mary Ramsay Brotchie, whom he met while she was nursing in Belvidere Hospital. They had two daughters and one son, who is a general practitioner in Lerwick, Shetland. We extend the sincerest sympathy to his devoted wife and family.—J. B.

A memorial service for the late Sir Archibald Gray will be held at the University Church of Christ the King, Gordon Square, London W.C.1, at 12 noon on Tuesday, 14 November.

News and Notes

EPIDEMIOLOGY

Fireworks Injuries

Last year there was a slight decrease from the previous year's total of firework accidents in England and Wales round about Guy Fawkes Day, but the number of patients admitted to hospital increased. Comparative figures in the table below are from the report of *Her Majesty's Inspectors of Explosives for the Year ended 31 December 1966, 1967, H.M.S.O.*

Fireworks Injuries in England and Wales During 16 October-12 November 1966 and Comparable Periods in 1962-5

Year	Total Accidents	Admitted to Hospital
1962	2,832	483
1963	2,461	332
1964	2,220	241
1965	2,339	213
1966	2,302	259

England and Wales in Third Quarter

The birth rate for the third quarter was 17.0, being 0.9 below the rate for the corre-

sponding quarter of 1966. The stillbirth rate at 13.9 per 1,000 total births was 1.2 below the rate for the preceding third quarter. Infant deaths were 17 per 1,000 live births. The general death rate was 9.8 per 1,000 of the population and was 0.1 above the rate for the preceding September quarter.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending 14 October (No. 41) and corresponding week 1966.

Figures of cases are for the countries shown and for Greater London. Figures of deaths and births are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire. A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

PARLIAMENT

Abortion Act will Become Effective Next April

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The Abortion Act is now law. It received the Royal Assent on 27 October, and will come into force six months from that date. The last comments in the Commons, who accepted the revised version which the Lords sent to them on 25 October, were to agree with this six-months interval so that the Ministry of Health can make the various regulations now necessary, and to adopt the changed title for the measure, which was introduced to them as the Medical Termination of Pregnancy Bill.

The Act includes the change, reported here in the House of Lords proceedings last week, and subsequently accepted by the Commons, enabling a doctor other than the two concurring in support of a termination, on the grounds stated, to perform the operation. There has also been added to the conscience clause a saving provision in respect of Scottish legal practice, which requires corroborative evidence of conscientious objection.

Balancing the Risks

One of the several subjects which has engaged members of both Houses during the protracted stages of this Bill has been the degree of risk involved in termination and the extent to which it should be taken into account as a factor in weighing the need for lawful abortion. It arose again during the concluding stages in the Lords on 23 October, and eventually resulted in a decision to reject qualifications such as "serious" and "substantial," and to adopt a formula proposed by the Lord Chief Justice, accepted by LORD SILKIN without consultation with or commitment to his co-promoters in the Commons, and ultimately endorsed in the House. This was to insert words in Clause 1 (1) (a) requiring the two doctors to be satisfied that the risks associated with a continued pregnancy would be "greater than if the pregnancy were terminated."

LORD PARKER OF WADDINGTON said of his amendment that he had been moved to suggest it when it became clear that what some people really wanted was to weigh the risks inherent in terminating a pregnancy against the risk of allowing it to continue. Only if the risk in continuation were greater than the risk in termination would a defence be created under the Bill. If that were the test it was unnecessary, and indeed would be wrong, to talk about risk as being "serious," "substantial," "real," or any words of that sort.

The doctors' decision, he added in a later intervention, was to be arrived at by comparing one risk with another.

Provisions of Act

The final form of the principal clauses of the Act is:

Medical Termination of Pregnancy

1.—(1) Subject to the provisions of this section, a person shall not be guilty of an offence under the law relating to abortion when a pregnancy is termi-

nated by a registered medical practitioner if two registered medical practitioners are of the opinion, formed in good faith—

(a) that the continuance of the pregnancy would involve risk to the life of the pregnant woman or of injury to the physical or mental health of the pregnant woman or any existing children of her family greater than if the pregnancy were terminated; or

(b) that there is a substantial risk that if the child were born it would suffer from such physical or mental abnormalities as to be seriously handicapped;

(c) in determining whether the continuance of a pregnancy would involve such risk of injury to health as is mentioned in paragraph (a) of subsection (1) of this section, account may be taken of the pregnant woman's actual or reasonably foreseeable environment.

(2) Except as provided by subsection (3) of this section, any treatment for the termination of pregnancy must be carried out in a hospital vested in the Minister of Health or the Secretary of State under the National Health Service Acts, or in a place for the time being approved for the purposes of this section by the said Minister or the Secretary of State.

(3) Subsection (2) of this section, and so much of subsection (1) as relates to the opinion of two registered medical practitioners, shall not apply to the termination of a pregnancy by a registered medical practitioner in a case where he is of the opinion, formed in good faith, that the termination is immediately necessary to save the life or to prevent grave permanent injury to the physical or mental health of the pregnant woman.

Conscientious Objection to Participation in Treatment

(1) Subject to subsection (2) of this section, no person shall be under any duty, whether by contract or by any statutory or other legal requirement, to participate in any treatment authorized by this Act to which he has a conscientious objection:

Provided that in any legal proceedings the burden of proof of conscientious objection shall rest on the person claiming to rely on it.

(2) Nothing in subsection (1) of this section shall affect any duty to participate in treatment which is necessary to save the life or to prevent grave permanent injury to the physical or mental health of a pregnant woman.

(3) In any proceedings before a court in Scotland, a statement on oath by any person to the effect that he has a conscientious objection to participating in any treatment authorized by this Act shall be sufficient evidence for the purpose of discharging the burden of proof imposed upon him by subsection (1) of this section.

[The Royal College of Obstetricians and Gynaecologists and the British Medical

Association were opposed to the section justifying abortion on the ground of risk to the physical or mental health of any existing children of the family—the so-called "social clause." They also considered that, of the two medical practitioners who must approve an abortion, one should be employed under the National Health Service as a consultant or be approved by the Minister of Health or the Secretary of State for Scotland.]

"Sans Everything" Inquiry

Mr. P. BESSELL (Lib., Bodmin) asked the Minister of Health on 27 October whether the name of the contributor to the book entitled *Sans Everything*, who made allegations of cruelty and neglect at St. Lawrence's Hospital, Bodmin, would be disclosed by the committee of inquiry to any person required to give evidence to the committee in respect of these allegations; whether the committee of inquiry would be empowered to disclose the nature of these allegations and their source to any members of the medical staff who may be required to give evidence during the course of the investigations; and to what extent he had verified the allegations before ordering an inquiry.

Mr. K. ROBINSON: I am not willing to confirm or refute assumptions about the identity of the hospitals which were the subject of allegations in *Sans Everything*, but where serious allegations of malpractice are made it is my duty to see that they are investigated. So far as *Sans Everything* inquiries are concerned, if a witness so indicates to one of the independent committees of inquiry his name will be revealed to no one except the members of the committee and its secretary, who will themselves observe complete confidentiality in the matter. Witnesses who wish to make allegations against named individuals must, however, be prepared to give evidence in the presence of the persons accused.

MEDICO-LEGAL

Agreed Reports

[FROM OUR LEGAL CORRESPONDENT]

The courts are continuing their efforts to reduce the time spent by professional men in giving evidence in court.

In a Practice Direction recently published¹ the President of the Divorce Division reminded lawyers of the desirability of disclosing to their opponents a copy of their expert's report in cases where expert evidence is to be called.

In the Divorce Division the expert will most usually be a doctor. Disclosure of the medical witness's report before trial will facilitate agreement that the report be read at the trial without calling oral evidence. Where the report cannot be agreed prior disclosure

will at least ensure that cross-examination is properly prepared and well-informed and directed at true points of issue.

The Practice Direction points out that where the expert evidence is that of a doctor it may frequently be expedient to incorporate or exhibit any relevant clinical notes, where necessary suitably explained. The exhibition of the material on which opinions are based should assist in the reaching of agreement on medical reports.

These considerations apply of course only to cases where a doctor is ethically free to disclose information before trial.

MEDICAL NEWS

Chair of Medical Statistics

Dr. DAVID JOHN NEWELL, Ph.D., has been appointed to a chair of medical statistics, personal to himself, at the University of Newcastle upon Tyne. Dr. Newell, who is 38,

went to Sidney Sussex College in 1949 after two years of National Service. He read Parts I and II of the Mathematics Tripos, graduating B.A. in 1952. The following year he was awarded the Cambridge diploma in mathematical statistics, with medical

statistics as a special subject. In 1961 he obtained the Ph.D. (Durham) after presenting a thesis "A Statistical Study of the Provision of Hospital Beds." From Cambridge he went to Newcastle in 1953 as medical statistician in the department of industrial health. He was promoted senior lecturer in biostatistics in 1962, and a year later was appointed to a personal readership. In 1959-60 he was visiting professor in the department of biostatistics at the University of North Carolina. A feature of his work has been his application of statistical methods to a range of medical problems that has included clinical research and administration.

Royal College of Surgeons of Edinburgh

At the annual meeting of the Royal College of Surgeons of Edinburgh, held on 18 October, the following office-bearers were elected: President, Mr. J. R. CAMERON; Secretary, Mr. J. A. ROSS; Treasurer, Mr. W. M. DRUMMOND.

Diploma in Aviation Medicine

The first examination for the diploma in aviation medicine (D.Av.Med.), which has been established by the Royal Colleges, will be conducted in July 1968. Copies of the regulations can be obtained free of charge from the Secretary, Examining Board in England, Examination Hall, 8-11 Queen Square, London W.C.1.

Romford Academic Medical Centre

Professor Sir JOHN MCMICHAEL, F.R.S., director of the British Postgraduate Medical Federation, opened the Romford Academic Medical Centre at Oldchurch Hospital, Romford, Essex, on 25 October. The centre provides for lectures, courses, clinical meetings, and formal and informal discussion. There is a conference and lecture room, laboratory, seminar and common rooms, and a library with space for study as well as for reference. In wishing the centre success Sir John predicted that practitioners in the area would continually turn to it for refreshment of knowledge and mutual education through the interchange of informed opinion and experience.

Commonwealth Foundation Awards

Grants totalling nearly £60,000 have been announced by the trustees of the Common-

wealth Foundation (see *B.M.J.*, 25 December 1965, p. 1556). The largest, £20,000, is to promote attendance of university representatives at the 10th Commonwealth Universities Congress in Australia in August next year. Other grants include £3,500 to the Commonwealth Society for the Deaf to meet the costs of a seminar in Nairobi on problems of deafness in Commonwealth Africa; £3,250 to the Uganda Medical Association in support of a project for refresher courses for up-country doctors; £2,500 to the Zambia Medical Association as a contribution to the costs of a regional Commonwealth meeting on aspects of tropical medicine; and £1,000 for an advisory visit to Africa by the secretary-general of the British Epilepsy Association.

Health Education Council

The Minister of Health has appointed BARONESS SEROTA to be chairman of the Health Education Council which the Government is setting up to organize the development of health education in England and Wales and Northern Ireland.

Nuffield Provincial Hospitals Trust

Over a million pounds has been spent by the Nuffield Provincial Hospitals Trust in the last three years on 181 projects covering almost every aspect of the health services in Great Britain. A special interest of the Trust has been the advancement of schemes for postgraduate medical education. By March this year, according to the Trust's triennial report, the investment in this field by way of grants amounted to £470,643, and a further £97,000 had been allocated by way of interest-free loans. Substantial sums have also been allocated to support projects relating to general practice, mental health, and the organization and operation of hospital and medical care services. An appendix to the report provides a list of projects, recipients of grants, and principals concerned.

Education in Psychology and Psychiatry

The need of general practice for doctors trained in psychology and psychiatry is described in a report by a working party appointed by the Royal College of General Practitioners (7s. 6d.). Having established the need, the report proceeds to consider in detail how it can be met, both before and after qualification, and to make recommendations. The present teaching of psychiatry in medical schools is analysed in an appendix. A leader on teaching the behavioural sciences was published in the *B.M.J.* of 21 October, p. 123.

Control of Drugs

Professor ARNOLD BECKETT, of the Chelsea College of Science and Technology, spoke on the subject "Drugs and Society" at the lunch given by the Royal Society of Health on 24 October. Professor Beckett commented on legislation proposed to control the safety, quality, and distribution of drugs, and warned that there was a danger of confusing the active principle and the drug preparation that is given to patients. The two were not synonymous. This had implications for the proposal to introduce generic names rather than brand names for new preparations. Despite careful quality control both within the industry and elsewhere there was no standard of biological availability of pharmaco-

logically active substances, said Professor Beckett. At the present time the responsibility for controlling availability rested with the pharmacological industry, but any measures to reduce the reward obtained by the manufacturers of a new preparation would at the same time discourage research into its properties that was not immediately profitable.

Research into Drug Addiction

A report on drug addiction published last week by the Office of Health Economics (2s. 6d. post free) observes that little large-scale co-ordinated research has been done in Britain. There is need, it says, for epidemiological studies to identify potential addicts with a view to prophylaxis. A key project would be to analyse the circumstances in which some cannabis users "progress" on to heroin addiction while others do not. Treatment and methods of rehabilitation are other subjects proposed for investigation, also the exact long-term effect of drugs on the human body. The report calls for more dependable statistics and for greater exchange of international research work. What may be needed, it suggests, is a Government-sponsored institute for the study of addiction to foster adequate research and facilities for the study and treatment of drug addiction.

Gift to British Heart Foundation

The British Heart Foundation has received £50,000 from Mr. HUGH SUMNER, former chairman of Typhoo Tea Ltd., of Droitwich, Worcestershire. It is one of the largest individual gifts made to the foundation.

Institute of Urology, London

Mr. HOWARD G. HANLEY has been appointed Dean of the Institute of Urology in succession to Mr. A. R. C. HIGHAM.

Experiment in Psychiatric Care

The Phoenix Group Homes, a voluntary organization in Colchester, Essex, provides care for ex-psychiatric patients who have nowhere suitable to live. In the houses that are rented or purchased the residents live independently except for a visit from a social worker every few days. There is no residential staff. The scheme is the product of co-operation between the hospital and local authority mental health services and is supported by the Gulbenkian Foundation. By the middle of next year some 36 to 40 people are expected to be accommodated. The chairman of the project is Dr. RICHARD FOX, Severalls Hospital, Colchester.

University Intake, 1967

In October this year the number of students entering undergraduate courses in universities in Great Britain through the Universities Central Council on Admissions was 49,000—about 5,000 more than in 1966. For universities in the United Kingdom the entry through U.C.C.A. was 50,500. In addition, there were between 6,500 and 7,000 students who gained university places outside the U.C.C.A. scheme, bringing the total number of new admissions to 56,000 for Great Britain and 57,500 for the United Kingdom as a whole.

People in the News

► LORD ADRIAN, O.M., F.R.S., has been nominated as Chancellor of Cambridge University in succession to LORD TEDDER.

► Major-General Sir NIGEL TAPP has been appointed Lieutenant-Governor and Secretary, Royal Hospital, Chelsea, London S.W.

► Professor JOHN W. DUNDEE, head of the department of anaesthetics at Queen's University, Belfast, is visiting South America this month under the auspices of the British Council.

► Professor J. H. MIDDLEMISS is visiting Jamaica as visitor to the University of the West Indies and as adviser in radiology to the Government of Jamaica.

► Mr. HAROLD EDWARDS, consulting surgeon to King's College Hospital, is giving a number of lectures in Pakistan under the auspices of the British Council.

► Mr. J. W. S. IRWIN has been appointed honorary consultant in surgery to the Army in Northern Ireland in succession to Sir IAN FRASER.

► Dr. J. A. ODDIE has been appointed senior administrative medical officer by the Oxford Regional Hospital Board. He succeeds Dr. J. O. F. DAVIES, now secretary of the Central Committee on Postgraduate Medical Education.

► Mr. DAVID A. SOLOMON has been appointed chairman of the Liverpool Regional Hospital Board from 1 April 1968.

News in Brief

Meldreth Training School, near Royston, Hertfordshire, was opened on 25 October by PRINCESS MARINA, DUCHESS OF KENT. It has been designed for spastics with multiple handicaps who cannot benefit from any other form of education. There are four houses, each accommodating up to 30 children. A central block provides treatment and educational facilities.

Christmas cards produced by various charitable organizations associated with hospital or health services are displayed at the Hospital Centre (24 Nutford Place, London W.1).

Grants and Awards

Dr. GEOFFREY CHAMBERLAIN was recently awarded the annual prize given by the American Association of Obstetricians and Gynecologists for research leading to a thesis entitled "An Artificial Placenta. The Development of an Extracorporeal System for Maintenance of Immature Infants with Respiratory Distress."

Coming Events

Medical Women's Federation.—Jubilee council meeting, 2-4 November, Manchester. Exhibition, "Women in Medicine," by Wellcome Historical Medical Museum and Library at the library, Manchester University. Admission without ticket.

Postgraduate Medicine, 1967 (T.V. Programme).—"Advances in Cardiology," Scottish Television, 6 November (11.50 p.m.), repeat 8 November (1.10 p.m.). "Growth in Childhood," Tyne Tees Television, 7 November (1.15 p.m.), repeat 12 November (10.15 a.m.).

Royal Medico-Psychological Association.—Autumn quarterly meeting, 16-17 November, in London. Programme includes seminars, papers, and section meetings. Details from General Secretary, R.M.P.A., Chandos House, 2 Queen Anne Street, London W.1.

National Association for the Welfare of Children in Hospital.—Conference, "The Child as a Long-stay Patient," 21 November, 10 a.m. to 12.30 p.m., Royal Commonwealth Society, Craven Street, London W.C.1. Opened by PRINCESS ALEXANDRA.

Society for Low Temperature Biology.—Symposium on blood preservation, 23 November, 2 p.m., Middlesex Hospital Medical School. Details from Secretary, Dr. DAVID E. PEGG, Clinical Research Centre Laboratories, National Institute for Medical Research, Mill Hill, London N.W.7.

King Edward's Hospital Fund for London.—Conference, "Making Better Use of Outpatient Departments and Accident and Emergency Units," 23 November, Hospital Centre, 24 Nutford Place, London W.1. Fee £1. Completed application forms by 13 November. This conference is the second of a series of three on making better use of hospital resources.

Royal College of Nursing and National Council of Nurses of the United Kingdom.—Conference, "Use and Abuse of Drugs," 23-24 November, Church House, Westminster. Sir GEORGE GODBER will give the opening address. Details from Conference Secretary, Royal College of Nursing, Henrietta Place, Cavendish Square, London W.1.

Institute for the Study and Treatment of Delinquency.—Week-end discussion course, "The Child, the Family, and the Institution," 24-26 November, Knuston Hall, near Wellingborough, Northants. Applications to General Secretary, I.S.T.D., 8 Bourdon Street, London W.1.

Societies and Lectures

For attending lectures marked ① a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Monday, 6 November

INSTITUTE OF DISEASES OF THE CHEST.—6.15 p.m., Dr J. Sutcliffe: Chest Radiology in Infants and Children.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Professor I. Friedmann, Dr. D. A. Osborn, Dr. M. I. Wright: clinicopathological conference.

INSTITUTE OF OBSTETRICS AND GYNACOBLOGY.—At Chelsea Hospital for Women, 3 p.m., discussion: Vaginal Hysterectomy. Speakers, Mr. J. Howkins, Professor J. Stallworthy.

KINGSTON-UPON-THAMES MEDICAL CENTRE.—5.15 p.m., Dr. E. Dowsett: The Body's Response to Viral Infection; 6.30 p.m., Dr. G. Stirling: Thrombosis.

MANCHESTER MEDICAL SOCIETY.—At Large Anatomy Theatre, Manchester University Medical School, 5 p.m., Dr. E. Boijesen (Lund): Selective Abdominal Arteriography.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Erasmus Wilson demonstration by Dr. W. D. Linsell: Granulomatous Lesions of the Myocardium.

ROYAL FREE HOSPITAL.—5.15 p.m., Dr. K. S. Holt: Present Thoughts on Assessment of Hearing Problems in Young Children.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Dr. W. A. Lishman: Psychiatric Aspects of Pain.

SCOTTISH TELEVISION LTD.—11.45 p.m., Advances in Cardiology. (Sponsored by Glasgow Postgraduate Medical Board.)

SOCIETY FOR MEDICAL AND DENTAL HYPNOSIS.—At Royal Society of Medicine, 8 p.m., Dr. J. C. Barker: Precognition and Aberfan.

Tuesday, 7 November

B.B.C. 2 TELEVISION.—1.15 p.m., medicine today: Low Back Pain. (Sponsored by A.S.M.E.)
BOLTON AND DISTRICT MEDICAL SOCIETY.—At Gymnasium, Bolton Royal Infirmary, 8.15 p.m.,

Professor R. B. Hunter: Treatment of Hypertension.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Professor D. W. Smithers: Clinical Research in Hodgkin's Disease.

INSTITUTE OF OBSTETRICS AND GYNACOBLOGY.—At Hammersmith Hospital, 2 p.m., Professor P. Rhodes: Management of Antepartum Haemorrhage.

MENTAL HEALTH RESEARCH FUND.—At Edward Lewis Theatre, Middlesex Hospital Medical School, 5 p.m., Sir Geoffrey Vickers: The Promotion of Psychiatric Research.

NEATH POSTGRADUATE MEDICAL CENTRE.—At Neath General Hospital, 4 p.m., joint medical, surgical, and anaesthetic presentation of a case.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., SOCIETY FOR THE STUDY OF ADDICTION.—At West Hall, Royal Society of Medicine, 8 p.m., discussion on Legalization of Marijuana. Speakers will include Mr. S. Abrams.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. H. C. Grant: Examination of the Brain.

WESTMINSTER MEDICAL SCHOOL.—At Meyerstein Lecture Theatre, 5.15 p.m., Mr. K. P. Robinson: Tumour Dissemination and Surgical Treatment.

WEST SUFFOLK HOSPITALS POSTGRADUATE CENTRE.—At Bury St. Edmunds, 1.15 p.m., Mr. R. E. B. Taggart: The Prostate Gland.

Wednesday, 8 November

ANGLO-CONTINENTAL MEDICAL SOCIETY.—At Royal Society of Tropical Medicine and Hygiene, London W., 8.45 p.m., Dr. K. R. Capper: Side Effects of Drugs.

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—(1) At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 12 noon, surgical meeting, (2) At Social Hall, St. John's Hospital, Wood Street, 12.30 p.m., obstetric conference, Mr. J. Moore: Spina Bifida and Allied Conditions of the Newborn.

INSTITUTE OF CHILD HEALTH.—At Kennedy Lecture Theatre, 5.30 p.m., Professor D. V. Hubble: Sex Problems in the Teenager.

INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. R. W. Riddell: Clinical Pathology of Ringworm Infections.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. D. C. Muir: Aerosol Deposition in the Respiratory Tract.

INSTITUTE OF UROLOGY.—5 p.m., Dr. R. C. B. Pugh: Pathology of Bladder Tumours.

MANCHESTER MEDICAL SOCIETY: SECTION OF PATHOLOGY.—At Large Anatomy Theatre, Manchester University Medical School, 5 p.m., Mr. H. Varley: Clinical Biochemistry in Manchester since 1902.

NORTHAMPTON GENERAL HOSPITAL.—8 p.m., Professor C. D. Calnan: The Skin and Autoimmunity.

OXFORD UNIVERSITY MEDICAL SCHOOL.—At Nuffield Maternity Home Lecture Theatre, Radcliffe Infirmary, 5 p.m., Professor R. R. Porter, F.R.S.: Very Recent Ideas on Structure and Origin of Antibodies.

ROYAL FREE HOSPITAL.—5.15 p.m., Dr. P. D. Marsden: Intestinal Parasites.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 11.45 a.m., clinicopathological conference by Dr. E. J. M. Campbell: Respiratory Failure. (2) 2 p.m., Dr. W. D. Alexander: Thyroid Function Test.

SCOTTISH TELEVISION LTD.—1 p.m., Advances in Cardiology. (Sponsored by Glasgow Postgraduate Medical Board.)

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At West London Hospital, 8.30 p.m., clinical meeting: Addiction. Speakers: Dr. M. Glatt, Dr. V. Marks.

WEST MIDDLESEX HOSPITAL.—At Lecture Theatre, 5 p.m., Sir Brian Windeyer: Medical Aspects of Radiotherapy.

Thursday, 9 November

ABERDEEN UNIVERSITY FACULTY OF MEDICINE.—At Large Lecture Theatre, University Medical Buildings, Foresterhill, 5 p.m., Dr. S. Browne: Leprosy—some outstanding problems and paradoxes.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Dr. J. L. Turk: The Cell Mediated Immunological Response.

DUNDEE UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Professor A. Duncan: What Kind of Doctors Should We Train?

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Virus Infections—Their Role in Otolaryngology.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 4 p.m., Mr. W. J. Dempster: Early and Long-term Changes in the Sectional Ureter. (2) 5 p.m., lecture on medical history by Dr. E. S. Clarke: History of Leprosy, Plague, and Syphilis.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright Fleming Institute Theatre, 5 p.m., Aleck Bourne lecture by Dr. F. P. Meehan: Caudal Analgesia in Obstetrics.

WESTMINSTER MEDICAL SCHOOL.—At Meyerstein Lecture Theatre, 5.15 p.m., surgical conference by Professor G. W. Taylor: Peripheral Vascular Disease.

Friday, 10 November

BROOK GENERAL HOSPITAL.—2 p.m., Dr. R. Hartley, Dr. M. Zoob: Cardiology—extended course.
KINGSTON-UPON-THAMES MEDICAL CENTRE.—3.30 p.m., obstetrics seminar by Dr. S. B. Kuğu: Lactation.
NORTHAMPTON MEDICAL SOCIETY.—8.30 p.m., Dr. Sheila Kenny: Problems of Intensive Care.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 10.15 a.m., Mr D. M. Wallace: There is No Place for Surgery or Radiotherapy in the Treatment of Bladder Tumours. (2) 11.30 a.m., clinicopathological conference. (3) 4 p.m., Dr. J. D. N. Nabarro: Idiopathic Hirsutism.
ST. MATTHEW'S HOSPITAL, London.—2.30 p.m., Mr M. J. Notaras: Faecal Incontinence in Elderly People.
WEST KENT MEDICO-CHIRURGICAL SOCIETY.—At Miller General Hospital, Greenwich, 8.30 p.m., Mr W. Mitchell: Art in Architecture.
WEST MIDDLESEX HOSPITAL.—4 p.m., Mr. D. Morris: Resuscitation of the Newborn.

Saturday, 11 November

MANCHESTER MEDICAL SOCIETY.—At Small Anatomy Theatre, Manchester University Medical School, 10 a.m., medical research papers.

Universities and Colleges**ROYAL COLLEGE OF PHYSICIANS OF LONDON**

At the quarterly comitia of the College held on 26 October, with the president, Sir Max Rosenheim, in the chair, Dr. T. C. Hunt was elected second vice-president; Dr. L. C. Marun, Dr. E. G. L. Bywaters, Dr. H. J. Wallace, and

Dr. R. I. S. Bayliss were elected councillors of the College.

Dr. C. E. Newman was elected College representative on the Committee of Management of the Examining Board. The president, Dr. K. Robson, Dr. R. S. B. Pearson, Dr. A. G. W. Whitfield, and Dr. J. Badenoch were elected members of the Standing Joint Committee of the three Royal Colleges.

The appointment of Dr. K. S. Holt as Milroy lecturer for 1969 was announced. His subject will be "The Quality of Survival." The award of the Jenks memorial scholarship to Dr. J. S. Carmichael was announced. The appointments of Dr. J. Waterlow as Charles West lecturer for 1968 and Dr. F. D. Hart as Philip Elham lecturer for 1969 were announced.

Licences

Licences to practise were conferred upon the following candidates:

D. F. Abbott, Penelope J. Aeberhard, R. W. G. Allison, J. A. R. Anderson, C. I. Andrew, N. M. Bannerman, R. H. J. Begent, J. K. Bell, M. C. Bishop, W. D. Biset, Marie H. L. Blankert, M. M. Bowen, Jennifer W. Bradburn, D. W. Branton, P. W. Briggs, J. B. Broadfield, J. K. Brockbank, R. J. S. Browne, N. Buchanan, G. W. S. Burgess, Gillian Carrington, R. S. Carruthers, J. H. Casson, A. P. Chakravorty, H. R. Champion, J. O. Clarke, Jerra Chubwala, J. Collier, J. R. O. Collin, Delia M. Crawley, J. P. J. Curran, Gillian R. Darch, J. P. M. Davies, J. H. W. Davies, T. P. Davis, Mara Dunis, N. R. V. Edmonds, Jennifer M. Edwards, C. G. Ellis, M. St. J. Floyd, Priscilla M. Fogarty, R. C. Freedman, K. Gopinatha Rao, Diane P. L. Gorvette,

Angela M. W. Greig, R. H. B. Grey, R. J. N. Gribble, A. W. Grieve, M. J. Griffiths, Susan J. Hall, Janet M. I. Hamilton, T. B. Hargreave, N. E. M. Harker, P. C. Harland, Carolyn Haworth, Margaret E. Hodson, P. J. Holt, I. M. Hutton, Bridget A. Jack, Gwyllyd W. B. J. Johnson, Katherine R. H. Johnson, R. W. Johnson, M. P. Jones, R. D. Jones, J. P. Kennedy Scott, Ruth M. Lacey, B. A. Leatherdale, S. I. Lewis, G. W. Libby, E. W. McLarty, G. P. H. Mason, M. A. Martin, Barbara M. Mawer, M. H. Mehta, D. R. V. Mercer, S. B. Merrill, D. P. B. Miles, R. Miller, C. J. Mitchell, Judy Moulds, G. H. Mumford, M. J. Myers, D. J. O'bome, V. O'Sullivan, W. D. Owusu-Yianomah, J. C. Pappin, H. R. Patel, J. Pemberton, E. H. Penry, Suzanne E. Powrie, A. Prakash, E. A. Proctor, D. H. K. Ratsey, H. R. D. Rawlinson, D. L. P. Rees, P. Renton, B. F. Ribeiro, D. N. G. Ridgway, K. H. Riding, F. P. Roberts, S. C. Robinson, S. G. Rubin, R. J. Sergeant, Z. K. S. Sharaiha, R. J. G. Soper, M. Spira, Jennifer T. Spring, Monica H. Spring, E. F. C. Stamp, J. B. Stevens, E. W. Taylor, J. G. Thomas, Margaret E. Tompsett, J. A. Townsend, M. G. Tweeddale, M. E. Twite, P. R. Vassal-Adams, R. C. Volkers, J. S. Walker, P. T. Walling, J. H. Walton, Hazel M. Watson, J. L. Watts, P. E. Watts, M. Webley, C. H. West, T. Wheeler, R. W. Whittlesey, Melanie Williams, P. D. Wimberley, T. R. Wykes.

Diplomas

Diplomas were granted jointly with the Royal College of Surgeons of England as follows:

DIPLOMA IN CHILD HEALTH.—L. A. S. A. Al-Kindi, E. J. J. Almeida, M. Aman, M. R. Baral, S. G. Benady, J. F. Branton, Gail C. Bridgman, J. Tin-Sui Chan, C. H. Cheetham, M. L. Chiswick, Margaret A. Cochran, D. W. D. Collure, P. P. Dawson, Gillian M. Day, C. J. Ellis, N. A. P. Evans, P. S. L. Fernando, W. O. Gbajumobi, A. Ghani, C. M. Gwynn, S. A. Haider, G. R. Hamilton, Josephine C. R. Harris, Elizabeth A. Harrison, A. J. C. Hawks, G. B. Haycock, S. S. Herman, Mary A. Hickey, P. Hickman, Linda M. Holland, Judith F. Hornby, J. K. Howell, S. K. A. Jafri, S. Jan, Devika S. Jayasuriya, J. R. Jelly, M. D. Kaye, A. S. S. I. Khan, M. J. A. Khan, S. P. Liyanage, S. E. G. Lubulwa, Erica R. McLerie, R. L. Mitchell, C. D. Molteno, Sarda-Ul Mulk, Margaret A. Muller, J. E. Ogwo, G. D. Osho-Williams, Christine A. Parr, Margaret R. Pendray, R. Prasad, Z. A. Qureshi, Leila Raju, K. Ramanathan, K. W. Rassam, T. S. Ravikant, R. P. A. Rivers, Wendy M. Rostron, H. B. Sahay, Katherine E. U. Salter, W. A. Saunders, Anna V. Seager, J. H. B. Sheppard, Jennifer M. Shobbrook, B. A. Sijuwade, Mary A. M. Slaughter, Carol M. Starkie, Suha W. F. Tappoun, J. R. Telfer, I. T. Thomas, A. M. Tucker, Louie A. Udai, Yat-Kwong Wong, C. J. E. Wynne-Williams, Priscilla M. Wooldridge, Kaniz Z. Zaidi.

Deaths

Adams.—On 23 October 1967, in Carlin House Nursing Home, Camberley, John Andrew Adams, M.B., B.Ch., B.A.O., formerly of Sowerby Bridge, Yorkshire, aged 100.
Mackay.—On 26 October 1967, at 5 Ravelston Park, Edinburgh, Angus Cameron Mackay, L.R.C.P., L.R.C.S., L.R.F.P.S. Glasg., of Creag Dhu, Connel, Argyll.
Townsend.—On 3 October 1967, at Kingswinford, Staffordshire, late of Kirk Ella, East Yorkshire, Tom Snowden Townsend, M.A., B.M., B.Ch., D.P.H., aged 73.

Correction

Infectious Hepatitis in Leicester 1963-6.—The final sentence of the summary of this article by Dr. C. Burns (23 September, page 773) should have read, "Most of the cases had illness of mild or moderate severity but three (0.31%) died."

New Issues of Specialist Journals

Obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London W.C.1.

JOURNAL OF NEUROLOGY, NEUROSURGERY AND PSYCHIATRY

Contents of the October issue are as follows:

Some Neuro-ophthalmological Observations. C. Miller Fisher.
 Median and Ulnar Neuropathy in the Guinea-pig. Pamela M. Fullerton and R. W. Gilliatt.
 Quantitative Electromyography Using Automatic Analysis: Studies in Healthy Subjects and Patients with Primary Muscle Disease. A. L. Rose and R. G. Willison.
 Enzymes of the Glycogen Cycle and Glycolysis in Various Human Neuromuscular Disorders. Salvatore Di Mauro, Corrado Angelini, and Claudia Catani.
 Studies of the Carrier State in the Duchenne Type of Muscular Dystrophy. Part I: Effect of Exercise on Serum Creatine Kinase Activity. Peter Hudgson, David Gardner-Medwin, R. J. T. Pennington, and John N. Walton.
 Phrenic Nerve Conduction in Man. J. Newsom Davis.
 Excitability of Motor Neurones in Spinal Shock in Man. E. Diamantopoulos and P. Zander Olsen.
 The Relation Between Chronic Polyneuropathy and Osteosclerotic Myeloma. J. B. Morley and A. C. Schwieger.
 Pheochromocytoma and Cerebellar Haemangioblastoma. R. D. Illingworth.
 Spinal Cord Embolism. Lionel Wolman and Peter Bradshaw.
 Hereditary Cataplexy. Jo-Ann M. Gelardi and Jason W. Brown.
 Longitudinal Movement of Radiolabelled Albumin Within Extravascular Spaces of Peripheral Nerves Following Three Systems of Experimental Trauma. Ross Mellick and J. B. Cavanagh.
 Combined Degeneration of the Spinal Cord Due to Deficiency of Alimentary Vitamin B₁₂. A. Verjaal and A. H. C. C. Timmermans-Van Den Bos.
 Tachistoscopic Number Estimation in Patients with Unilateral Cerebral Lesions. Elizabeth K. Warrington and Merle James.
 Book Reviews.

Volume 30, No. 5. Yearly subscription (6 numbers) £4 4s., abroad £4 15s.

GUT

Contents of the October issue are as follows:

Obituary: Henry A. Magnus, F. Avery Jones.
 Hepatic Scintigraphy. E. A. Jones.
 Pancreatic Scanning. Ian A. D. Bouchier.
 Rectal Biopsy as an Aid to Cancer Control in Ulcerative Colitis. B. C. Morson and Lillian S. C. Pang.
 Primary Sclerosing Cholangitis, the Biliary Tree, and Ulcerative Colitis. M. E. C. Thorpe, P. J. Scheuer, and Sheila Sherlock.
 Studies on the Familial Incidence and Clinical History of Patients with Chronic Unconjugated Hyperbilirubinaemia. Paul M. Smith, J. E. Middleton, and Roger Williams.
 Zinc and Manganese Levels in Serum and Liver after Alcohol Feeding and Development of Fatty Cirrhosis in Rats. Anthony J. Barak, Harriet C. Beckenhauer, and Felix J. Kerrigan.
 Observations on Oral Betamethasone-17-valerate in the Treatment of Idiopathic Steatorrhoea. A. T. Otaki, J. R. Daly, and A. Morton-Gill.
 Motor Responses of the Human Alimentary Tract to Near-maximal Infusions of Pentagastrin. J. J. Misiewicz, D. J. Holdstock, and Sheila L. Waller.
 Analysis of the Motor Effects of Gastrin and Pentagastrin on the Human Alimentary Tract in vitro. A. Bennett, J. J. Misiewicz, and Sheila L. Waller.
 Gastric Response to Subcutaneous Injection of a Gastrin-like Pentapeptide. K. G. Wormsley, M. P. Mahoney, and G. Kay.
 Serum Proteins in Ulcerative Colitis: Electrophoretic Patterns in the Inferior Mesenteric Artery and Vein. F. T. de Dombal.
 Changes in the Motility of the Small Intestine in Digestive Disorders. F. Pirik.
 Histochemistry of the Colonic Epithelial Mucins in Normal Subjects and in Patients with Ulcerative Colitis. V. Greco, G. Lauro, A. Fabbrini, and A. Torsoli.
 The Antrum in Patients with Duodenal and Gastric Ulcers. J. Schrager, R. Snink, and S. Mitra.
 Limitation of the Use of Inert Gases in the Measurement of Small Gut Mucosal Blood Flow. J. D. Hamilton, A. M. Dawson, and Joan Webb.
 Gastroenterological Society of Australia.

Volume 8, No. 5. Yearly subscription (6 numbers) £4 4s., abroad £4 15s.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: Antiology, London W.C.1. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1. on receipt of proofs.

ADVERTISING AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY 11 NOVEMBER 1967

Pointers

Cross-infection: Predisposing factors, treatment, and prophylaxis against recurrence of respiratory infection due to *Ps. aeruginosa* in a cardiac surgery unit described (p. 313). Leader at p. 309.

Respiratory Tract Infection: Management in children, particularly by antibiotic and biochemical measures, and report of investigation into 22 fatal cases (p. 316). Leader this page.

Complications of Triple Vaccination: Survey in Sweden shows an apparent increase in number of neurological reactions, but severe reactions leading to permanent injury seem to have decreased (p. 320).

Burkitt's Lymphoma: Long-term survival rate in Mulago Hospital, Uganda, is markedly dependent on the anatomical involvement at presentation, although there may be a relation to drug used and its dosage (p. 323).

Hyperaldosteronism: Discussion of a fourth case of a syndrome characterized by hypokalaemia, glomerular abnormalities, normal blood pressure, and absence of oedema (p. 327).

Parathyroidectomy in Renal Failure: This may produce healing of bone lesions due to secondary renal hyperparathyroidism, and may avoid calculus formation in a transplanted kidney if surgery is performed at an early stage (p. 331).

"Acrosclerosis": Three cases of sclerodactyly, Raynaud's phenomenon, calcinosis, and telangiectasia (p. 334).

Case Reports: Incest and mental ability (p. 336); Unusual cause of tongue pain (p. 337); Diagnosis of bacterial endocarditis (p. 338).

Body Building: Hazards of self-medication with anabolic steroids (pp. 310 and 353).

Dyspepsia: Indications for surgery and type of operation in duodenal ulcer (p. 339).

Low Back Pain: Article complementing television programme shown on 7 November and to be repeated on 15 November (p. 341).

Alcoholism Information Centres: Discussion of use of these centres and the type of people visiting them (p. 346).

Epidemic Keratoconjunctivitis: Lanarkshire outbreak (pp. 353 and 366).

Administration of N.H.S.: Minister to study possibility of further integration (p. 367).

Pay-beds: Number reduced by 1,385 (p. 367).

G.M.S. Committee: Meeting report (*Supplement*, p. 43).

Universities and Armed Forces: Salaries to go to Prices and Incomes Board (*Supplement*, p. 48).

Respiratory Infection in Early Childhood

During the last 30 years mortality from respiratory disease in childhood has fallen considerably. But many problems remain. Some of them are discussed by Dr. P. S. Gardner and his colleagues at Newcastle upon Tyne in their article which appears at page 316 of this week's *B.M.J.* The authors hasten to point out that the 22 children whom they studied and who died as a result of acute respiratory diseases formed a selected group, not necessarily representative of this age as a whole. But this detracts little from the value of the article, since by a careful analysis of the histories and findings the authors are able to suggest possible ways of improving both diagnosis and treatment. With the approach of winter their warnings are timely.

Bacterial diseases were responsible for only six of the 22 deaths, and of the viral diseases bronchiolitis was much the most important. The infant with bronchiolitis is characteristically restless and distressed, with a repetitive, exhausting cough and rapid wheezy respirations, which, although accompanied by much effort, are ineffective. Obstruction of distal airways, with trapping of air, results in acute emphysema. This clinical picture differs considerably from that of the infant with pneumonia, nowadays often due to organisms highly resistant to antibiotics. Like bronchiolitis pneumonia is often preceded by brief upper respiratory symptoms, but wheezing is less marked, the rapid respirations are frequently accompanied by grunting and cyanosis, and tachypnoea and tachycardia are often out of proportion to the physical findings in the chest, especially in small infants. A high pyrexia is suggestive of a bacterial pneumonia. In both these conditions the infant may deteriorate suddenly, either from respiratory insufficiency or from a complication such as the pyopneumothorax which is commonly seen in children with staphylococcal pneumonia.

Another important condition which Dr. Gardner and his colleagues encountered was *Haemophilus influenzae* epiglottitis, and they rightly stress the importance of early diagnosis in this disease. It should be immediately suspected if a fiery red oedematous epiglottis is seen over the base of the tongue when examining the fauces of a child with croup. Prostration and collapse rapidly occur, either from inspiratory obstruction or from the septicaemia often present. Pertussis, though not included in the conditions reported, remains a danger to infants despite the reduction in mortality from this disease. In less severe cases the paroxysmal cough may resemble that of mucoviscidosis, but when more severe it may be accompanied by life-threatening periods of apnoea. Associated congenital abnormalities were found in 9 of the 22 children studied at Newcastle. Disproportionate degrees of tachycardia, cyanosis, or hepatomegaly should lead the physician to consider congenital heart

disease. Treatment today offers a much better prognosis in mucoviscidosis than formerly,¹ and the possibility of this condition should be borne in mind in all infants with bacterial pneumonia.

The most important requirement in the management of infants with severe respiratory infections is adequate oxygen therapy. This aspect is well discussed in the article by H. Simpson and D. C. Flenley,² to which Dr. Gardner and his colleagues refer. Simpson and Flenley stress the importance of cyanosis in assessing severity. They also point out that the risk of inducing carbon dioxide narcosis in young children requiring oxygen therapy is apparently negligible. Inspiratory oxygen concentrations will frequently need to be considerably in excess of 40%, a figure which in practice is often not achieved in oxygen tents now available.³ Severe hypoxia may result if the oxygen concentration falls suddenly,⁴ and care is therefore essential when attending to children who are being nursed at high concentrations of oxygen. As in the adult, repeated blood gas analyses must be undertaken for the correct management of severe degrees of respiratory insufficiency. Thus Simpson and Flenley suggest that a *pH* below 7.2 or *PCO*₂ above 65 mm. Hg might be suitable indications for giving parenteral bicarbonate or intermittent positive pressure respiration or both. Though the value of tracheostomy in bronchiolitis has been questioned,⁵ some children have been shown to benefit.⁶ Complications are common after this procedure, however,⁷ and nasotracheal intubation appears to be a preferable alternative.^{8,9} This too is not entirely without its problems, and it appears that it is preferably restricted to children with lower respiratory diseases.¹⁰ These aspects of management are highly specialized and will be possible only in hospitals with facilities for intensive care, the requirements for which were discussed by Drs. D. Campbell, J. M. Reid, A. B. M. Telfer, and W. Fitch in the *B.M.J.* last week.¹¹

The place of antibiotics in bronchiolitis was discussed in these columns two years ago.¹² As it is a viral infection, they will be of value only in preventing or treating the rare¹³ but disastrous secondary infection. The correct choice may be difficult, but it is necessary to recognize that infants who were born in hospital, and especially those who have already received broad-spectrum antibiotics, are likely to harbour organisms highly resistant to antibiotics. No time should therefore be lost in testing bacterial sensitivities in any infant thought to have pneumonia, and therapy should include a penicillinase-resistant antibiotic such as cloxacillin. Tetracycline or chloramphenicol are suitable antibiotics for use in *H. influenzae* epiglottitis, and chlortetracycline is a useful prophylactic for an unprotected infant who comes into contact with pertussis.

Other aspects of therapy which may play a part in these severe diseases of early childhood include attention to fluid

and electrolyte balance, mist therapy,¹⁴ and correct position for nursing. Cautious sedation with, for example, chloral hydrate is often indicated for the restless infant with bronchiolitis after hypoxaemia has been corrected. The value of corticosteroids in bronchiolitis is doubtful,¹⁵ but the occasional severely ill infant appears to derive benefit.

Cowpox and Paravaccinia

People whose daily work brings them into contact with farm animals are especially liable to develop bacterial infection such as brucellosis or rickettsial infection such as Q fever. It is less well known that they are also exposed to the risk of viral infections of the skin which may be acquired from cattle or sheep. The viruses concerned belong to the large group of poxviruses. The most important poxvirus in human disease is variola or smallpox virus, but this does not affect any animal species other than man. However, man is susceptible to other poxviruses whose natural hosts are cows and sheep.

Jenner's classic treatise in 1798¹ contained the first description of human cowpox, which at that time was not uncommon among dairymaids. Cowpox causes vesicles on the teats and udders of cows, and they progress to pustules, with the formation of scabs. It is a mild infection in that animal, and the disease is spread mainly by the process of milking. Cases of human cowpox are rarely reported, but A. W. Downie² found 10 outbreaks in cattle in England and Wales during 1944 to 1950, and in each instance attention was drawn to the disease by cases of infection in milkers. In 1909 R. J. Reece investigated an outbreak in Somerset which involved 23 out of 44 milkers and 214 out of 410 cows.³ More recently W. F. T. McMath and H. T. H. Wilson described a case in this journal⁴ of a young man who developed multiple lesions on the chin and lips from contact with an apparently healthy calf.

Human cowpox usually affects the hands—often between the thumb and forefinger—but lesions are sometimes seen on the forearm and face. The lesions are vesicular and closely resemble the reactions seen after successful vaccination against smallpox. Cowpox vesicles tend to be more haemorrhagic than vaccination reactions, and the vesicle fluid may be blood-stained. The lesions are painful and are usually associated with lymphangitis and lymphadenitis. There is often a mild constitutional upset, with some fever. The lesions are slow to heal and may take several weeks to resolve. The vaccinia virus used for vaccination against smallpox is very similar to cowpox virus and probably originally derived from it. Both have the brick-shaped particles on electron-microscopy which are seen with smallpox virus also. Cowpox and vaccinia have a similar range of susceptible hosts, and there have been outbreaks of cowpox in cattle due to infection introduced by a recently vaccinated person.⁵

In addition to cowpox, cattle are susceptible to other poxviruses that can infect human skin. These are members of the paravaccinia subgroup of poxviruses and include the virus of milker's nodules, bovine papular stomatitis virus, and the virus of orf or contagious pustular dermatitis in sheep.⁶ Paravaccinia viruses have oval particles on electron-microscopy with characteristic criss-cross surface banding, so that they resemble coiled skeins of wool.⁷ The virus of milker's nodules affects the teats and udders of cows, causing lesions

which clinically bear some resemblance to those of cowpox. Orf produces lesions in the mouths of sheep and is mainly seen as an infection of lambs. The third paravaccinia virus—bovine papular stomatitis virus—is now thought to be the same virus as that causing milker's nodules.⁸ Bovine papular stomatitis has recently been reported in Britain⁹ and causes lesions which are clinically similar to milker's nodules on the hands and forearms of human handlers.^{8 10 11}

Human infection with the paravaccinia viruses of orf and milker's nodules is not uncommon in rural areas. Infection is seen in people who have contact with cows or sheep or with products derived from them. For example, orf is seen in shepherds, butchers, sheep shearers, and veterinary surgeons and has been described in housewives with a liking for sheep's heads.¹²⁻¹⁹ Milker's nodules are also seen in veterinary surgeons and in farm workers who tend dairy cattle—even if the animals are milked by machine.^{5 20 21} Both viruses cause similar disease in man, and the name ascribed to the infection depends on the animals which were the probable source of infection.²⁰ As a result, orf is diagnosed in shepherds and milker's nodules in cowmen. Clinically the lesions are usually single, but cases with two or with multiple lesions have been reported. The fingers and hands are the commonest sites for them, but lesions have been described on the arms, face, neck, and occasionally on the leg. Different types of lesion may be seen. Most start as bluish-red papules or nodules, which are sometimes surmounted by a small white blister. Ulceration is common. Lesions may also take the form of granulomas in which there is ulceration with proliferation of grey-coloured epidermal tissue. Many appear to be vesicular, but it is often difficult to extract fluid from them.²² The most striking feature is that the lesions are painless, though they look like acute inflammatory reactions. There is usually no constitutional disturbance. Lymphangitis and lymphadenitis have been described, but—in contrast to human cowpox—appear to be rare. The lesions persist for about five to eight weeks and resolve spontaneously without treatment. One attack appears to confer long-lasting immunity against reinfection, but, unlike cowpox, there is no cross-immunity with vaccinia.^{22 23}

The relationship between the three paravaccinia viruses is obscure, though it is clear that they are closely related. J. Nagington and his co-workers have shown that orf and

milker's nodules viruses are similar in their morphology and cultural characteristics.²⁰ In addition I. M. Lauder and his colleagues have shown that the bovine virus of milker's nodules can produce lesions in lambs after inoculation on to the gums and lips.²⁴

Neither cowpox nor paravaccinia is a serious infection in man. Diagnosis will present few problems to general practitioners in rural areas or to dermatologists, who also see these diseases from time to time. However, the infections might well puzzle a newly qualified casualty officer in a city, who may come across lesions on the hands of butchers, slaughtermen, or veterinary surgeons. When the infection has been diagnosed, the patient can be reassured—firstly as to the nature of the lesion, and secondly that it will resolve spontaneously and without complications within the following month or two.

Pseudomonas Infection in Hospital

In the last few years the problems of staphylococcal cross-infection seem to have become more manageable, thanks especially to the semisynthetic penicillins tolerant of penicillinase. Unfortunately the same cannot be said of infection with *Pseudomonas aeruginosa* (pyocyanea). Indeed, reports of such infections have become more frequent. This can be partly explained by the relative ineffectiveness of chemotherapy for pseudomonas infection. Successful treatment of infections with Gram-positive cocci has undoubtedly brought the less tractable infections with Gram-negative bacilli such as *Ps. aeruginosa* into prominence. A relative and absolute increase in the amount of infection by these opportunists appears to have occurred.¹⁻³

Epidemiological features of pseudomonas infection which have made it hard to eradicate⁴ include its tendency to grow or at least survive in moist environments and its relative insensitivity to certain disinfectants as well as to most antibiotics. Moreover, despite a low pathogenicity for healthy people, it tends to be more pathogenic and invasive than most other common bacteria in patients or in tissues with low humoral resistance—for example, in infants and in leukaemic patients, in the chambers of the eye, and on the meninges. Not surprisingly, *Ps. aeruginosa* is a special hazard to patients treated with corticosteroids and with immunosuppressive drugs.³⁻⁵ In burned patients two factors encourage pseudomonas infection—the presence of moist slough, which is easily colonized by *Ps. aeruginosa*, and (when the burns are extensive) reduced resistance to invasion.

The sources of these infections are varied and often elusive. Unlike *Escherichia coli* and *Staphylococcus aureus*, *Ps. aeruginosa* is usually not carried in large numbers by healthy people. Recent studies⁶ have shown a larger proportion (about 12%) of healthy people to be carrying *Ps. aeruginosa*, at least in small numbers, than most previous surveys had suggested, and in another recent report⁷ about 5% of healthy people were found to carry *Ps. aeruginosa* in the saliva. But, while sporadic self-infection with *Ps. aeruginosa* can undoubtedly occur, most endemic infection such as in burns and all outbreaks can be attributed to contamination from another human source or the inanimate environment. In many cases the source has been traced by typing of strains.⁸⁻¹⁰ Human sources are generally sites of heavy infection—wounds, burns, the urinary tract. Established inanimate

sources include saline,¹¹ soap and antiseptic solutions,¹² eyedrops,¹³ creams,¹⁴ jellies,¹⁵ and equipment which contains standing water or retains moisture (especially respirators and resuscitation equipment for premature infants),¹⁶⁻¹⁷ moist brushes (for example, shaving-brushes used for depilation of the scalp before craniotomy),¹⁸ and surgical instruments and catheters "sterilized" with an inadequate disinfectant.^{19 20} Dry sources (dust, air) are uncommon but may on occasion be important.²¹ The hands of nurses in wards where the infection occurs are often found to carry *Ps. aeruginosa* and are likely to contaminate uninfected patients if the nurses do not wear rubber or plastic gloves when attending to them.²² The importance of some sites which are commonly contaminated—for example, sinks and drains—has not been clearly established.

At page 313 of the *B.M.J.* this week Dr. J. E. Tinne, Dr. A. M. Gordon, Mr. W. H. Bain, and Mr. W. A. Mackey report an outbreak of infection of the respiratory tract with *Ps. aeruginosa* in a cardiac surgery unit. During two months, in which 30 operations were performed, five patients became infected with this organism and three of them died. These deaths occurred in the eight patients of the series who had open heart surgery followed by tracheostomy, hydrocortisone therapy, broad-spectrum antibiotics, and prolonged mechanical ventilation. All strains were of the infrequent pyocine type 10. A strain of the same type was found in the connecting tube of a respiratory ventilator and in a rebreathing bag. These findings strongly suggest that infection was acquired by the patient's respiratory tract from the ventilator. The authors subsequently found *Ps. aeruginosa* on various fittings and pieces of equipment in the operating-theatre suite, and introduced measures to prevent recurrences. These included the use of a new disinfectant, which appeared to be effective in removing *Ps. aeruginosa* from contaminated objects and sites.

Though outbreaks of *Ps. aeruginosa* infection continue to be reported, they are often due to some deficiency or error in technique (especially in sterilization or maintenance of sterility) which can be corrected. But outstanding difficulties still exist with types of equipment—for example, mechanical ventilators—that cannot be sterilized by heat, and also with the elaborate nursing procedures of intensive-care units. The design of some types of equipment needs improvement to facilitate cleaning and disinfection. In the treatment of burns the control of *Ps. aeruginosa* infection has been greatly helped by local application of 0.5% silver nitrate solution,^{23 24} and this can probably be enhanced by modern aseptic methods, notably the use of "isolators"^{25 26}—that is, special isolation chambers. Two new antibiotics, gentamicin^{25 28} and carbenicillin,²⁷⁻²⁹ give promise of providing better control of *Ps. aeruginosa* infection than has been obtained with the polymyxins, and immunological methods of protection have also shown promise.^{30 31} For the protection of high-risk patients it is desirable to use these and other methods in a system of multiple defences. But no set of rules can succeed without a high standard of aseptic discipline and understanding among the hospital staff under the guidance of an active infection-control officer.

Body Building by Drugs

The self-administration of anabolic steroids is becoming a problem in athletics. A letter from Dr. D. E. Pearsons at page 353 draws attention to the matter. Taking these artificial aids to athletic performance must surely be condemned as unethical. In addition, it is possibly hazardous to health, for this group of drugs have side-effects.

Those anabolic steroids that are active when taken by mouth commonly affect conventional liver-function tests and occasionally cause jaundice. These side-effects are probably caused by interference with the transport of conjugated compounds into the bile and usually disappear quickly on withdrawal of the drug. Serum enzyme levels of the transaminases S.G.O.T. and S.G.P.T. and lactic dehydrogenase are often raised, though this does not necessarily imply damage to liver cells. Only the compounds active by mouth cause liver damage, because of their particular chemical configuration. They may also raise the level of serum lipids, especially of cholesterol, with the possibility of causing serious harm in that way. This action has been specially noted in two groups of patients—those receiving glucocorticoids and obese diabetics not requiring insulin.¹ Some anabolic steroids may impair the hepatic degradation of cortisol, enhancing the action of this drug and necessitating a reduction in dosage.^{2 3}

All anabolic steroids so far investigated have proved to have some androgenic activity. In women this may lead to hirsuties, acne, and virilization of the voice.⁴ The patient feels her voice to be strange and is unsure about its use; in severe cases it wavers between the chest and falsetto registers. This effect is irreversible.

Increased muscular development and improved athletic performance are widely believed to result from use of anabolic

steroids,⁵ and there is good evidence that they do increase the muscle mass in castrates of both sexes and in most patients with a high rate of protein catabolism, but critical studies confirming these effects in normal men on an optimal protein and calorie intake are lacking. In a carefully controlled trial W. M. Fowler and colleagues⁶ failed to find any effect of an anabolic steroid on the physical performance of young healthy men, even in a group taking extra physical exercise along with the drug. It might be argued that the physical exercise used in this study was not severe enough to compare with that undertaken by athletes preparing for international competition. If that were so it is possible that anabolic steroids combined with a high-protein diet might have an anticatabolic effect under conditions of severe muscular exercise, and hence produce an increase in physical performance.

It is difficult to detect whether a patient is taking these preparations, because the doses used might be small, and in any case adequate methods for detecting these drugs and their metabolites in blood and urine have not been fully evaluated. Since any effect they may have on muscular development will be prolonged, athletes can stop taking the drugs several weeks before a competition, so that any chance of detection then would be negligible. Secondary effects of the anabolic steroids on serum enzyme levels or on the level of thyroxine-binding globulin,⁷ with lowering of the plasma protein-bound iodine, might be more prolonged, but further studies are required to clarify their duration. It is to be hoped that all the governing bodies of sports will take a stand against the use of such methods of training.

Mismanagement of Non-disease

Some two years ago C. K. Meador¹ wrote an amusing but important article entitled "The Art and Science of Non-disease," drawing attention to common errors of diagnosis in the endocrine field, with resulting treatment of nonexistent disease. Some of the mistakes were due to laboratory errors. "Laboratory error syndromes," he wrote, "are the delight of the alert non-disease clinician; one must add, however, only before therapy has been initiated. In this regard they are probably the most responsive to treatment of all entities. One merely has to repeat the test once to see astounding results; for example, in what other non-disease or disease can one see a rise in the haemoglobin level from 6 to 14 g./100 ml. in two hours with only one iron tablet?"

Recently A. B. Bergman and S. J. Stamm² have discussed morbidity of cardiac non-disease in schoolchildren. They studied 93 children who were said to have had rheumatic fever or to have "something wrong with the heart." Seventy-five (81%) had nothing wrong with them—and thirty of these had been subjected to severe restrictions on the instruction of their doctor. Eighteen had organic heart disease, and six of them had been put under severe but unnecessary restrictions. They wrote that "Restriction of children with innocent murmurs is only slightly more absurd than restriction of the vast majority of children with an organic heart defect"; and "The diagnosis of heart disease may cause profound changes in the functioning of a child and his family, far beyond the immediate physical effects." On the basis of their

study of these 93 children they concluded that "The amount of disability from cardiac non-disease in children is estimated to be greater than that due to actual heart disease." They rightly criticize the restrictions imposed on children with congenital or acquired heart disease, advocating that they should be left to find their own level of activity of which they are capable. Parents fear that their child will drop dead if allowed to cry or to exert himself in other ways. In fact, as the writers state, sudden death is rare except in children with aortic stenosis.

Functional murmurs are exceedingly common in children. R. W. Quinn and E. S. Campbell³ found them in 44% of 4,039 Nashville schoolchildren. Unfortunately it is not easy to describe in words the difference between a functional murmur and the murmur of organic disease. The distinction is a matter of experience. In general, the functional murmur is louder when the child is lying down, it is increased by exertion, and it has a musical, twanging nature, or is very soft. Murmurs in the newborn period frequently suggest serious congenital heart disease to the unwary, only to disappear in a few days. The venous hum, the to-and-fro murmur beneath the clavicle, can easily lead the doctor towards the diagnosis of a patent ductus arteriosus, while the true nature of the murmur could be readily established by causing its disappearance on rotating the head or by pressure on the vessels of the neck. The tachycardia of excitement or nervousness and the raised systolic blood pressure under the circumstances of the doctor's examination can likewise lead to the wrong diagnosis of cardiac disease.

Now R. S. Illingworth,⁴ of Sheffield, has tried to dispel "Fallacies in Four Fevers." Discussing measles, German measles, chicken-pox, and mumps, he questions the value of some of the time-honoured methods of managing children with these infections and quotes with approval N. L. Browse's remark that "the bed is often a sign of our therapeutic inadequacy."⁵ Certainly many doctors as well as parents would agree with Illingworth that too long confinement to bed of children with these fevers can do actual harm and give no benefit. He is likewise critical of the isolation and medication of these patients on principles that may be long accepted but have escaped careful scrutiny. When prescribing treatment, he says, one should always ask three questions: What good may it do? What harm may it do? What harm may be done by not giving this treatment?

Oesophageal Function in Diabetes

Among the better-known neurological complications of long-standing diabetes are peripheral neuropathy, impotence, diarrhoea, and postural hypotension. The exact nature of the neurogenic defect is still a matter of debate, and the effects are often complex and are not necessarily clinically apparent. In the gastrointestinal tract, for example,^{1,2} symptomless gastric atony can result in a radiological appearance similar to that produced by vagotomy,³ whereas diarrhoea in some patients may be associated with steatorrhoea or with changes in bowel flora.⁴

Rather surprisingly, little attention has been paid to the oesophagus. W. R. Rundles,⁵ in a classic review of diabetic neuropathy, mentioned the finding of degenerated nerve plexuses in the oesophagus of two patients, but there has been no detailed investigation of oesophageal function. A recent report⁶ shows that oesophageal abnormalities may in fact be fairly common. Fourteen patients with evidence of diabetic neuropathy were examined by cineradiography, and 12 had evidence of dysfunction. Peristalsis was reduced or absent, emptying was delayed, the oesophagus was dilated, and tertiary contractions were seen. Two patients had oesophageal reflux and hiatus hernia. No abnormalities were found in 14 matched control subjects. In spite of the frequency of radiological findings, only three patients had symptoms, consisting of heartburn in one and dysphagia in two.

These results are similar to previous investigations of other parts of the gastrointestinal tract, in which a high incidence of radiological abnormalities contrasts with the paucity of clinical symptoms. In addition, there was no correlation with the degree of diabetic control, with other evidence of visceral neuropathy, or with other complications of the disease. One patient with severe dysphagia died, but the oesophageal nerve plexuses appeared normal. The enigmatic nature of diabetic neuropathy, in which disorders of function may be found without either recognizable pathological changes or the production of symptoms, presents a challenge to the physician. In the case of the oesophagus further insight might be provided by the use of intraluminal manometry.

Ventricular Aneurysm

For the past quarter of a century radiologists have recognized that after myocardial infarction there are commonly abnormalities of ventricular contraction. These have been reported in as many as 70% of an unselected group of patients with both old and fresh myocardial infarcts,¹⁻³ and may take the form of paradoxical pulsation of a localized segment of the cardiac silhouette or of diminished or absent pulsation. Serial kymographic studies have shown that in some patients these abnormalities disappear or become less marked with healing of the infarct.

The advent of cineventriculography has made it easier to study disturbances of ventricular contraction. Using this technique R. Gorlin and his colleagues⁴ found abnormalities of contraction in about 20% to 25% of patients with coronary artery disease who were being assessed before the operation of implantation of an internal mammary pedicle. In Gorlin's study the term ventricular aneurysm was used to describe abnormalities of local movement of the ventricular wall, whether or not these were associated with thinning or fibrosis.

This definition of aneurysm is mechanical rather than anatomical and is probably too great an extension of the traditional meaning of the word. A more acceptable definition is that of J. Schlichter and his colleagues,⁵ who defined a cardiac aneurysm as a localized outpouching of the cavity of a cardiac chamber with or without outward bulging of the external surface—in either case a large transmural infarct leads to thinning of the left ventricular wall and consequent paradoxical pulsation. If Schlichter's definition of aneurysm is accepted a different term will be needed for the reversible abnormalities of ventricular contraction without a full thickness infarct described by Gorlin and his coworkers.

Abnormalities of ventricular contraction after myocardial infarction can usually be recognized at the bedside. Careful palpation of the cardiac impulse will detect the development of a sustained abnormal impulse appearing during the first week after acute cardiac infarction in about one-fifth of patients.⁶⁻⁸ Recognition of this simple physical sign can be made without the aid of graphic recording by simultaneous palpation and auscultation. If a sustained outward impulse is felt, lasting up to the time of the second heart sound, this is abnormal. Where this sign persists after acute cardiac infarction strong presumptive evidence of a ventricular aneurysm exists, provided there was not already left ventricular hypertrophy due to co-existing hypertension or aortic valve disease. The site of greatest excursion of the abnormal impulse varies with the site of the aneurysm. If it is anterior the impulse is usually greatest somewhere over the mid-praecordium. If, however, the aneurysm is postero-lateral then the abnormal impulse is usually confined to the apex. The surest evidence that the sustained impulse is related to the infarction rather than to previous left ventricular hypertrophy is observation of its development during the first week after acute infarction. Graphic records confirm the abnormally sustained nature of the impulse and usually show a double hump due to a large palpable preceding atrial beat. Apex cardiography is an unreliable method of recording late systolic events, as it is influenced by the pressure with which the pick-up head is applied to the moving chest wall; but absolute displacement techniques such as impulse cardiography⁹ and kinetocardiography¹⁰ give faithful records. When the diagnosis of cardiac aneurysm has been suggested by the presence of an abnormal cardiac impulse, it can be confirmed by fluoroscopy and electrocardiography. Angiocardiography is of value in detailed preoperative investigation.

D. L. Abrams and his colleagues¹¹ in a review of 65 consecutive cases of ventricular aneurysm at necropsy recommended a conservative approach to treatment. Their main indications for ventriculoplasty were progressive heart failure refractory to medical therapy, where coronary arteriography showed the blood supply to the rest of the ventricle was adequate; and repeated systemic embolization that could not be controlled by treatment with anticoagulants. The highest mortality from cardiac aneurysm is within the first year, and is caused by intractable heart failure. If patients survive this period the prognosis does not appear to be very different from that of ischaemic heart disease in general.

The next session of the General Medical Council will open on Tuesday, 28 November, at 2.15 p.m., when the president, the Rt. Hon. Lord Cohen of Birkenhead, will take the chair and will deliver an address.

Cross-infection by *Pseudomonas aeruginosa* as a Hazard of Intensive Surgery

J. E. TINNE,* M.D., B.SC., D.P.H., M.C.PATH.; A. M. GORDON,* M.B., D.PATH., M.C.PATH.

Brit. med. J., 1967, 4, 313-315

Although cross-infection has always presented serious problems, there has within recent years been an increased awareness of the growing prevalence of Gram-negative organisms, especially *Pseudomonas aeruginosa*, as causes of serious morbidity in the hospital environment (Finland *et al.*, 1959; Williams *et al.*, 1960; Barber, 1961). A variety of factors appear to have contributed to this changing pattern of hospital-acquired bacterial infections, but the extensive use of broad-spectrum antibiotics, corticosteroids, and cytotoxic and immunosuppressive drugs, and the increased susceptibility of individuals subjected to advanced and intensive surgery or medical techniques, have been of major significance. In this context, infections by *Ps. aeruginosa*, an organism of low pathogenicity to healthy individuals, are likely to be particularly serious and associated with a high mortality. This opportunist has an inherently high resistance to most currently available antibiotics, and many antiseptics are less active against *Ps. aeruginosa* than against other vegetative bacteria.

Recently a series of *Ps. aeruginosa* infections of the respiratory tract occurred in a cardiovascular surgical unit involving seven patients, three of whom died. The three fatal cases had been subjected to open-heart surgery followed by intensive care, including tracheostomies and prolonged postoperative mechanical ventilation. They had also received corticosteroids, while all the cases had had prophylactic broad-spectrum antibiotic cover.

This paper describes the clinical and bacteriological features of the outbreak together with the epidemiological investigations and control measures which were undertaken.

History of the Initial Outbreak

During the two months December 1966 to February 1967 30 operations were performed in the unit. Twenty-two were mitral valvotomies or other short closed-heart procedures, and none of these showed any evidence of respiratory or wound infection. On the other hand, of the eight patients who underwent open-heart surgery with extracorporeal circulation, five developed respiratory tract infections due to *Ps. aeruginosa* and three of these subsequently died. The following is a synopsis of the postoperative course of the first five cases in which *Ps. aeruginosa* was isolated.

Case 1.—This patient's operation was for closure of an atrial septal defect. He was breathing spontaneously immediately after the operation, and subsequently his course was uneventful apart from a respiratory infection. Culture of his sputum on the fourth day grew *Escherichia coli* (sensitive to ampicillin, streptomycin, and tetracycline) and *Ps. aeruginosa* (sensitive to colistin only). The patient made a good recovery.

Case 2.—An aortic valve (Starr) prosthesis was inserted in this man on 12 December, after which intermittent positive-pressure ventilation by Bennet's machine was required and a tracheostomy was performed two days later. *Ps. aeruginosa* was cultured from his bronchial aspirate during the subsequent 10 days, and he died of progressive respiratory insufficiency and septicaemia.

Case 3.—This boy had an operation for closure of an atrial septal defect on 19 January 1967 and required a tracheostomy for respiratory insufficiency on 21 January, and ventilation was assisted. Four days later *Ps. aeruginosa* was grown from specimens of tracheal aspiration and he died three weeks after operation.

Case 4.—Another operation for closure of an atrial septal defect took place on 2 February 1967. Though the postoperative course was uncomplicated by clinical evidence of infection, culture of sputum on the fifth day revealed *Ps. aeruginosa*. This was an isolated specimen, however, and subsequent cultures were negative. The patient made a good recovery.

Case 5.—An operation for replacement of the mitral valve was carried out on 6 February 1967. Tracheostomy was performed for respiratory insufficiency on 8 February and ventilation was assisted mechanically. Culture of tracheal secretions on each of the next three days showed a heavy growth of pseudomonads. Blood cultures on the fourth and fifth days also grew *Ps. aeruginosa*. The patient died on the sixth day after operation.

On reviewing the postoperative course of these cases, certain common factors emerge. It has been routine practice in this unit to administer ampicillin and methicillin by slow intravenous drip for seven days after open-heart surgery. Further, the three patients who died had received comparatively large doses of hydrocortisone (500 mg. six-hourly) throughout the first postoperative week in an effort to modify the "post-perfusion lung" syndrome. While the three patients who died were certainly the most ill from the point of view of their cardiovascular status, it might also be argued that the combination of the antibiotics used, together with continued large doses of hydrocortisone, rendered them unduly susceptible to an overwhelming infection by *Ps. aeruginosa*.

Bacteriological Investigations and Control

It will be noticed that all five cases had had tracheostomies. This operation is notorious for profoundly modifying respiration and so exposing the lung to pseudomonas infection (Dupont *et al.*, 1962), and this risk is much greater when the artificial airway has to be prolonged, as *Ps. aeruginosa* is about 10 times commoner in the secretions collected after a month than in those taken after a week (Tunevall, 1956). Moreover, all the cases had been given ampicillin and methicillin prophylactically, and *Ps. aeruginosa*, resistant to these antibiotics, was present in the sputa of all seven cases; it was also found in the tracheostomy wounds of two of the fatal ones (Cases 2 and 5) and in the throat, bronchi, and blood of one (Case 5) at necropsy.

* University Department of Bacteriology, Royal Infirmary, Glasgow C.4.
† University Department of Surgery, Royal Infirmary, Glasgow C.4.

These findings suggested a respiratory source for the infection, and this was confirmed when random swabbing of the equipment of the theatre suite and adjacent rooms showed that at this stage isolation of pseudomonads was limited to the anaesthetic equipment, and in fact to the connecting tube of the Bennet ventilator and the Ambu rebreathing bag.

Wahba (1965) showed that by identifying the specific pyocines produced by the pseudomonads it was possible to distinguish different strains, and, using 12 such indicators, he differentiated eight strains. Gillies and Govan (1966), using only eight pyocine indicators, identified 36 types, of which Nos. 1, 3, 5, 6, and 9 comprised over 70% of all *Pseudomonas* strains they tested. With this technique Dr. Gillies was able to confirm that the strain of *Ps. aeruginosa* found in the ventilator and the Ambu bag was the relatively rare type 10 identical to that also found in the three fatal cases.

The respiratory equipment had come under suspicion after the second case. The Ambu bag was destroyed and sterilization of the ventilator attempted by washing with chlorhexidine digluconate followed by exposure to ethylene oxide by running the gas through the machine. Solutions of chlorhexidine have recently been incriminated in the actual spread of pseudomonads in a hospital (*Brit. med. J.*, 1967; Burdon and Whitby, 1967). The last three of these five cases were infected by *Ps. aeruginosa* after the anaesthetic equipment had been treated by both methods before use in each case. Clearly these methods of disinfection were ineffective. Moreover, the organism had by now contaminated the distilled water in the nebulizer of the Bennet ventilator and also the alternative Barnett ventilator, the connecting tube being again implicated as well as the flowmeter, which was found to contain blood clotted on the vanes when dismantled.

Pseudomonas aeruginosa was recovered from the throat swabs of 6 of the 50 staff and patients, and it was suspected that the organism, which would not normally be a commensal in this site, had become widely disseminated.

For our earlier isolations of pseudomonads we had relied on the selective medium of Lowbury and Collins (1955) which employs 0.03% cetrinide; and to eliminate *Klebsiella* and *Proteus* spp., which also survive, we had depended on pseudomonal colonies giving a positive oxidase test, rather than the improved fluorescence of the organism which Brown and Lowbury (1965) achieved by modifying the medium. As it was intended to culture numerous swabs from the theatre and surroundings, the cetrinide plates were made even more selective by adding 5 µg. of nalidixic acid per ml. This was based on a clinical trial (Barlow, 1963) in which 24 out of 25 strains of *Pseudomonas* had resisted nalidixic acid inhibitory to *Klebsiella* and *Proteus* spp. in cultures of urine. Experiments showed that our *Ps. aeruginosa* type 10 could just survive these combined inhibitory agents, which together excluded other bacteria.

Several hundred moistened swabs were now used to sample the flora on the fittings and equipment of the theatre and adjoining rooms. *Ps. aeruginosa* was isolated from the following relatively inaccessible places even after the use of various disinfectants, which had included glutaraldehyde, and chlorhexidine with cetrinide: ventilator of ceiling light; ventilator louver on wall; panel of air-conditioning control on wall; trap and gauge of suction apparatus on wall; corrugated tubing of Boyle's anaesthetic apparatus; sampling tube and undersurface of chassis of Astrup blood-gas analysis trolley; grids on drains of floor and sink; a pair of clogs; and in adjacent rooms the x-ray camera, and the drains of the dark-room, ward, and sluice.

It was obvious that there was particularly widespread contamination with *Pseudomonas* sp., and it had to be assumed that nothing short of their complete eradication would ensure elimination of the risk from the epidemic of type 10. A solution of activated glutaraldehyde has been recommended by

Rittenbury and Hench (1965) for sterilizing anaesthetic equipment such as masks, suction catheters, and endotracheal tubes; but Ross (1966) found that at a concentration of 50% this compound required between 15 and 30 minutes to kill pseudomonads in broth, and that with added blood even this was insufficient. It is problematic whether any disinfectant can be relied on with gross contamination with blood, but the timely appearance of a new disinfectant Portex-DCR containing diphenidol which was reputedly active against pseudomonads enabled us to test this agent, using a broth culture of the type 10 organism and a similar broth culture with 10% blood added. The results showed that Portex-DCR killed the pseudomonads in two minutes at a dilution of 1/160 in broth, but that in the presence of blood 1/40 was the effective dilution. This agent offers two further advantages: it is non-irritant in effective dilutions; and it changes colour from green to blue when no longer active—this indicator is a useful guide under circumstances where the solution is being applied by lay staff such as cleaners.

The unit was closed and the six nurses with positive throat cultures were sent on a week's leave. Intricate equipment was dismantled, cleaned, and then sterilized by 24 hours' exposure to ethylene oxide in plastic bags; but all other appliances and the rooms themselves were disinfected by washing with 1/40 Portex-DCR. As this still left surviving pseudomonads, notably in the drains and the Astrup blood-gas analysis apparatus, this washing was repeated with 1/20 Portex-DCR, and lysol was poured down the drains. Pipes and ducts were flushed for 30 minutes with Trilene to remove oil deposits. It was found, however, that the organism survived 25 minutes' exposure to this detergent, and therefore the Trilene was followed by washing with Portex-DCR 1/20. Two months elapsed before complete clearance was reached for all equipment and personnel, some equipment having to be dismantled by the makers to dislodge an organism described as "notorious for its ability to survive in unlikely situations" (*Lancet*, 1961).

Reappearance of Infection—Cases 6 and 7

On 15 May 1967 a housewife (Case 6) who had been admitted for mitral valve replacement produced a purulent sputum infected with *Ps. aeruginosa* type 10, raising doubts whether disinfection had been effective. Inquiry showed, however, that she had been in the ward during the first half of December 1966, when she would have encountered the infection and might well have harboured it since. Colistin was added to her prophylactic methicillin and ampicillin, and the sputum was cleared of pseudomonads after a week, though not before a patient in the adjoining bed (Case 7) had shown transient cross-infection. Closure of an atrial septal defect on this man 10 days previously had necessitated a tracheostomy, and on 15 May 20 colonies of *Ps. aeruginosa* were isolated from his tracheal secretions on a single occasion. Colistin methanesulphonate 1.5 mega units eight-hourly was given for three days and there was no recurrence.

Discussion

The distinction between pathogenic bacteria and harmless saprophytes, traditional since the days of Koch, has become blurred in recent years, and a survey at Boston City Hospital (Finland *et al.*, 1959) showed that between 1935 and 1957 intestinal commensals had progressively replaced the pyogenic cocci isolated from cases of bacteraemia. Moreover, the analysis disclosed that before 1941 *E. coli* alone was responsible but that after that date *Klebsiella*, *Proteus*, and *Pseudomonas* spp. increased in frequency. Secondary infection of wounds by *Ps. aeruginosa* has long been recognized because it will often colour the pus, and as skin and nasal carriers are relatively rare in contrast to those bearing staphylococci (Barber, 1961;

Williams *et al.*, 1966) cross-infection from other cases had to be assumed. Indeed, Selwyn *et al.* (1964), investigating 1,231 cases of hospital infection in Edinburgh, found that no less than 70% were non-staphylococcal, and they concluded that there had been comparative neglect of the role of these other organisms and especially of "coliform bacilli," including *Ps. aeruginosa*.

Opportunists such as these, though normally less invasive than the pyogenic cocci, are also far less fastidious in growth, so that their destruction is a formidable challenge to both antiseptics and antibiotics. Two ecological hazards are inseparable from the use of antibiotics. One is the emergence of resistant mutants, which has already become a major problem with the hospital staphylococcus; the other is disturbance of the diversity of bacterial flora. With "broad-spectrum" antibiotics only the hardier organisms will survive, and *Pseudomonas* is perhaps the hardiest of all. Widespread and even autochthonous, this organism is essentially a saprophyte and its normal habitat in man is limited to the intestine, and even in this situation its presence is exceptional (Lowbury and Fox, 1954).

Although human susceptibility to *Ps. aeruginosa* has been shown by random serological tests (Jones and Lowbury, 1965) to be very variable, certain groups would seem to be gravely at risk. Ayliffe *et al.* (1965) attributed cases of meningitis and urinary and wound infections in a neurosurgical unit to pre-operative use of a shaving brush infected with *Ps. aeruginosa*, and similarly contaminated eye-drops accounted for pseudomonal infection of 15 out of 25 ophthalmic operations, in six of which there was loss of the eye (Ayliffe *et al.*, 1966).

Phillips and Spencer (1965), who described 10 medical cases of respiratory infection with *Ps. pyocyanea*, four of which were fatal, noted that, ordinarily, the organism is virtually absent from human sputum, not one of 347 routine samples containing pseudomonads. Eight of their cases were infected like ours by a ventilator, two being cross-infections in adjoining beds, and they noted the role of prophylactic antibiotics, tracheostomy, and corticosteroids also in predisposing to infection.

In the present series of eight cases one or other of these three factors (corticosteroids, broad-spectrum antibiotics, and tracheostomy) again played a part, and in the three fatal cases all were present.

Though *Pseudomonas* sp. were found distributed in inaccessible sites ranging from the ceiling light to the drains the infections were primarily respiratory, and the fortunate chance of a relatively uncommon pyocine type being involved clearly implicated the ventilator and the rebreathing bag.

That droplet and dust-borne infections may not in practice be a risk from other sources was confirmed by experiment. While the theatre was closed 18 settle-plates were exposed for an hour on the floor and fittings. For 10 minutes of this time a surgeon, anaesthetist, and four nurses wearing masks and gowns talked and moved about the theatre, being asked to locate the plates. Notwithstanding that two of the team had positive nose or throat swabs for *Ps. aeruginosa* and that these organisms still persisted on the floor grid to the drains, no pseudomonads settled on the plates. We believe that carriers play little part in an epidemic of pseudomonal infection, but that even a single major case, especially respiratory, may contaminate the entire environment to such a degree that eradication becomes very difficult indeed.

Cetrimide-nalidixic acid plates and pyocine typing were found to be valuable tools in tracing the source and mode of spread of pseudomonads, just as modern disinfectants were needed for the control. Portex-DCR 2% proved to be the disinfectant most effective against *Ps. aeruginosa*, acting even in the presence of blood, unlike its rivals, though up to 10% was necessary *in vitro* in the presence of gross contamination. This was supplemented by ethylene oxide fumigation of electrical

and other intricate equipment and by Trilene irrigation for ducts. No disinfectant is likely to succeed, however, in the eradication of pseudomonads that are being harboured in blood-clot and other protein debris; and, as Phillips and Spencer (1965) found, there is still need for a practical filter to protect anaesthetic equipment. Such a filter would need to have really easy access to disposable pads so that they could be replaced constantly as they became sodden. In the absence of such filters we raised the Barnet ventilator to a level above the patient's head to minimize the contamination of the apparatus by gravity. Expedients suggested by others have been to place a filter on the intake tube of the ventilator (Bishop *et al.*, 1963) or to put chlorhexidine in its humidifier unit (Phillips and Spencer, 1965); but none of these precautions deals with what is probably the prime source of infection, the patient himself who originally infected the machine.

There may be an additional argument here for adding colistin to the prophylactic antibiotics recommended for cases on intensive care, but its nephrotoxicity must be borne in mind. There are certainly good grounds for monitoring the sputum of all such cases on admission and before and after operation. By using cetrimide-nalidixic acid plates we were able to screen heavy inocula, and we felt well justified when this procedure detected *Ps. aeruginosa* in the respiratory tracts of the last two cases. It showed that it is possible to get early warning of what might have become recrudescence of infection by this most formidable organism.

Summary

An outbreak of respiratory infection in a cardiac surgery unit affected seven cases, with three deaths. *Pseudomonas aeruginosa*, type 10, the causative organism, was also isolated from the anaesthetic equipment.

Possible predisposing factors were tracheostomy, corticosteroids, and prophylactic antibiotics.

Measures taken to prevent a recurrence included screening of sputa on a selective medium and the use of an efficient new antiseptic containing dipenidam.

We wish to thank Dr. J. C. J. Ives for his advice, and Mr. W. Forbes for his help. Dr. R. R. Gillies and Mr. J. R. W. Govan kindly undertook the pyocine typing, and we are grateful to Mr. J. D. Campbell, Miss Robina Spence, and Miss June Harley for skilled technical assistance. Messrs. Portland Plastics provided urgent supplies of Portex-DCR containing dipenidam (Messrs. Alan Glasby).

Brit. med. J., 1967, 4, 316-320

The number of children who die from respiratory tract infections has decreased markedly during the period in which antibacterial drugs have become available. The figures given in Table I illustrate this point clearly, but they also show that such deaths have by no means been eliminated and that the extent of the improvement is much less among infants than among older children.

TABLE I.—Numbers of Children Who Died in Newcastle upon Tyne from Lower Respiratory Tract Infections

Age in Years	No. of Deaths During			Approximate Ratio of Deaths 1931-5 to 1961-5
	1931-5	1946-50	1961-5	
<1	416	206	73	6:1
1-4	294	24	6	50:1
5-14	52	6	5	10:1
Total	762	236	84	9:1

This table is based on figures for deaths from bronchitis or pneumonia given in the appropriate Annual Reports of the Medical Officer of Health for the City and County of Newcastle upon Tyne. Virtually all deaths from non-tuberculous lower respiratory tract infections were included under these two diagnoses.

In the course of an extensive survey of respiratory tract infection in children in the Newcastle area we have obtained information about 22 children with such infections who died during the period October 1964 to December 1966 and who fulfilled the following conditions: that they were admitted to hospital before they died; that they came to necropsy; and that bacteriological and virological investigations of their infections were carried out either before or after death, or both. We have analysed our data in an attempt to find out why these children died, and have paid particular attention to information on three subjects: the presence of conditions which might have made the children unduly liable to succumb to infection; the nature of the infecting organisms; and any features of the children's clinical conditions which might suggest the mechanisms of death and measures that might have prevented it. These children are admittedly a selected group; "cot deaths," for example, were excluded by our criteria. Our information is incomplete at many points, but it is sufficient to provide a valid, even though only a partial, picture of respiratory tract infection as a continuing threat to the lives of young children.

Methods of Investigation

In addition to clinical examination and assessment the children were investigated as follows:

Bacteriology.—Nasal and cough swabs for bacterial culture were collected from 13 children shortly after they were admitted to hospital. No such swabs were collected from the other nine, many of whom died within a few hours of admission, but blood cultures were set up from two of them before they died. Heart and lung punctures were carried out within 15 minutes after death in 11 cases; the resulting fluids were inoculated into Robertson's cooked meat medium, which was placed in a 37° C. incubator as soon as possible

and was subcultured to solid media when visible growth occurred. Necropsy tracheal or lung swabs were collected in 13 cases. In one case a small amount of broth was injected submucosally into the swollen epiglottis at necropsy and then withdrawn and used for inoculating cultures for *Haemophilus influenzae* (Jones and Camps, 1957).

Virology.—Nasal and cough swabs collected from 11 children shortly after admission were transported to the laboratory and examined there as previously described (Elderkin *et al.*, 1965). Lung tissue for virus culture was collected at necropsy, up to 48 hours after death, in 21 of the 22 cases. Such tissue was homogenized in 10 times its own volume of medium 199 and then lightly centrifuged, and the supernatant fluid was used for inoculating tissue cultures. The cell lines used for cultures of swabs and of lung tissue were HeLa, Hep II, rhesus monkey kidney, and human diploid cells (W.I.38).

Pathology.—Seven pathologists carried out necropsy examinations of children in this series, but two of us, who had carried out nine of the necropsies, each examined histological sections of lung from all 22 cases. Final pathological classification of respiratory tract conditions was based on the following combinations of findings: *epiglottitis*—oedema, hyperaemia, and neutrophil infiltration of the epiglottis; *bronchitis*—mucosal oedema, enhanced mucus formation, and neutrophil infiltration confined to the bronchi; *bronchiolitis*—inflammatory exudate in the intralobular air passages but little or none in the surrounding pulmonary alveoli, the inflammatory cells being in some cases mainly neutrophils within the lumina and in other cases mainly lymphocytes within the walls of the bronchioles; *pneumonia*—inflammatory exudate and infiltration involving the pulmonary alveoli. We hope to publish elsewhere further details of the pathological findings in the lungs.

Findings

Nine of the 22 children were boys and 13 were girls. Eighteen were 6 months old or less and only three were more than a year old. Most of the illnesses were short—three days or less in eight cases and four to seven days in seven cases. Eleven children died within 24 hours of admission to hospital, four of them within the first two hours.

Classification of the patients according to the findings shown in Table II. provides a satisfactory basis for a description of the main features of their illnesses. This is followed by a review of the treatment given and of certain additional aspects of their conditions to which we wish to draw attention.

Twenty-two Patients Classified According to Pathological and Microbiological Findings

The first six children (Cases 1-6) apparently died from bacterial infections. The first two had staphylococcal pneumonia with characteristic multiple lung abscesses. One of them (Case 1) had a pyopneumothorax when she reached hospital five days after the onset of her illness; she died two days later. The other (Case 2) did not receive any medical attention for nearly a week after he became ill; he died one hour after reaching hospital.

The child with epiglottitis (Case 3) was moribund when he reached hospital, having been treated for cardiac arrest during

* From the Departments of Virology, Microbiology, Pathology, and Child Health, the University and the Royal Victoria Infirmary, Newcastle upon Tyne, and the Institute of Pathology, Newcastle General Hospital.

the journey, and his breathing was maintained by positive-pressure ventilation from the time of his admission. He had had a mild coryzal illness for about a week but had been seriously ill for only a few hours—a common sequence of events in this often lethal disease (for references see Turk and May, 1967). *H. influenzae* type b, the expected causal agent, was isolated at necropsy from this child's grossly inflamed and swollen epiglottis, but an additional and unexpected finding was the isolation of respiratory syncytial virus (R.S.V.) from his upper respiratory tract before death and also from his necropsy lung specimen.

A 1-month-old infant with multiple congenital haemangiomas of her face and liver (Case 4) died within 12 hours of becoming seriously ill with streptococcal septicaemia and pneumonia, probably secondary to infection of her facial lesions.

Each of the two remaining children in this group (Cases 5 and 6) had for several weeks before death received continuous antibiotic treatment for bacterial superinfection of pulmonary mucoviscidosis; and in each case highly antibiotic-resistant bacilli, such as had been found in the upper respiratory tract during life, were isolated from tracheal swabs taken at necropsy and were thought to have been responsible for the terminal pneumonia. Details of the antibiotic treatment are given below.

One child (Case 7) was admitted to hospital two days after she became ill. She had pneumonia, with radiological appearances suggesting that it was staphylococcal. She seemed to make good progress on treatment with cloxacillin and ampicillin, but eight days after admission she suddenly collapsed and died. Necropsy revealed that as well as pneumonia, which was showing evidence of resolution, she had an unexplained area of myocardial necrosis, and this was thought to have been responsible for her death.

Four children (Cases 8 to 11) all had pneumonia for which no bacterial cause was found. All were ill for less than five days, and all died within a few hours of admission to hospital. R.S.V. was isolated from necropsy lung specimens in every case. Two of the children had congenital heart abnormalities—endocardial fibroelastosis (Case 10) and a large ventricular septal defect associated with mongolism (Case 11)—and one (Case 9) was found at necropsy to have acute myocarditis.

Nine children (Cases 12 to 20) had bronchiolitis. In seven the illness lasted only two to five days; one of these (Case 16) had previously undergone right upper lobectomy for congenital emphysema. One child (Case 13) had been treated with tetracycline for bronchitis three weeks before admission, following which she vomited blood and remained unwell, with diarrhoea. When she came into hospital with an exacerbation of her respiratory tract condition two days before she died she was markedly dehydrated, and at necropsy was found to have a sagittal sinus thrombosis as well as bronchiolitis. The

remaining child (Case 15) had a patent ductus arteriosus and an atrial septal defect and had been intermittently ill for six of his 12 weeks of life; he died two days after admission. R.S.V. was isolated from three of these nine children.

Two children (Cases 21 and 22) collapsed and died unexpectedly while under treatment for what appeared to be relatively mild respiratory tract infections, of 19 and 11 days' duration respectively. In each case the only respiratory tract abnormality found at necropsy was a mild bronchitis, not apparently sufficient to explain death; but one child, a mongol, was found to have a small atrial septal defect and the other to have endocardial fibroelastosis. R.S.V. was isolated from the upper respiratory tract of the first of these two children before he died.

Antibiotic Treatment

Only seven of the 22 children had been treated with antibiotics before coming to hospital. The two with mucoviscidosis had both received penicillins. One of them (Case 5), who had had phenoxymethylpenicillin for two days before admission, was treated with benzylpenicillin and cloxacillin throughout her three weeks in hospital and with polymyxin B (to which her *Pseudomonas* was sensitive *in vitro*) for the last four days. The other (Case 6) had been on ampicillin for several weeks before admission, and received benzylpenicillin, cloxacillin, and chloramphenicol during her five days in hospital; her *Proteus* was resistant to the penicillins but chloramphenicol-sensitive. Five children had been treated with tetracyclines before admission. These included one with staphylococcal pneumonia and pyopneumothorax (Case 1), who had been so treated for two days and who received cloxacillin (to which her staphylococcus was sensitive) and benzylpenicillin for the two days that she was in hospital; the child mentioned above as having had tetracycline three weeks before admission (Case 13), who received cloxacillin and chloramphenicol during her two days in hospital; and three others (Cases 11, 17, and 22) whose tetracycline treatment had lasted for one to three days and who died within 12 hours of reaching hospital.

Six of the 15 children who received no antibiotics before coming to hospital (Cases 2, 4, 8, 9, 14, and 20) died within 12 hours of admission, and the details of their treatment are thus of little importance. The child with haemophilus epiglottitis (Case 3) was treated with an appropriate antibiotic (ampicillin) but was moribund before this treatment began. It seems likely that one child (Case 7) was being successfully treated for staphylococcal pneumonia with cloxacillin, as already described, when she died from myocardial necrosis. The remaining seven children (Cases 10, 12, 15, 16, and 18–20), received benzylpenicillin, cloxacillin, ampicillin, tetracyclines, or combinations of these drugs for periods of between

16 hours and five days, but there is no evidence that they were suffering from bacterial infections.

Among the patients with no bacterial explanation for their infections (Cases 8–22) there were only four who had received antibiotics (tetracyclines in every case) before coming to hospital.

Other Forms of Treatment

All 22 children were treated with oxygen at some time, either in tents or by intermittent positive-pressure respiration. Intravenous fluids were given to five, including three who were hyperpyrexial on admission (rectal temperature 105° F. (40.6° C) or more). Ice-packs were used in treatment of one of these and of two other hyperpyrexial children. (In contrast to these, eight children had rectal temperatures of 100° F. (37.8° C.) or less on admission; we have found no correlation between temperature levels and pathological or microbiological findings.) Nine children were given digoxin for cardiac failure; these included four of the seven children with congenital or acquired heart lesions, but not the two whose cardiac abnormalities were unsuspected before necropsy (Cases 21 and 22) nor the child with a ventricular septal defect (Case 11) whose hopeless condition on arrival in hospital is described below. Eight children received hydrocortisone or prednisone; further information about six of these is given below.

Mode of Death

As indicated in our introduction, we have been concerned to discover not only why these children died—that is, the aetiology of their fatal illnesses—but also how they died, in the hope of seeing whether their lives could have been saved by measures other than those which were employed.

Cardiac Arrest.—This occurred in three cases. The heart of the child with a patent ductus arteriosus (Case 15) stopped suddenly while she was undergoing bronchoscopy for treatment of massive pulmonary collapse, having been successfully treated in this way twice in the preceding 24 hours; cardiac massage was ineffective. The heart of the child with epiglottitis (Case 3) also stopped suddenly, while he was on the way to hospital, but it responded to massage; however, he never breathed spontaneously after admission, and by the next day had ceased to show any evidence of cerebral function. One other child (Case 19) had a similar story except that his heart stopped and was started again by external massage on four occasions during his last three days.

Cardiac Failure.—One child (Case 10) suddenly became deeply cyanosed and showed signs of cardiac failure several hours after admission. He was treated with digoxin and hydrocortisone but died 10 hours later. Necropsy confirmed that he was in cardiac failure as well as having pneumonia, and also revealed that he had endocardial fibroelastosis. (As already stated, eight other children were treated for cardiac failure, but in none of these cases was it a principal cause of death.)

Sudden Collapse.—Thirteen children collapsed suddenly, becoming pale, hypotonic, and unresponsive to stimuli, with shallow irregular or gasping respirations but without cardiac arrest. These 13 included only one of the six children whose deaths were apparently due to bacterial infection. This child (Case 1) and six others (Cases 7, 8, 12, 16, 21, and 22) all died within minutes of collapsing. The remaining six children in this group (Cases 9, 13, 14, 17, 18, and 20) survived for periods ranging between one hour and two days; four of them were treated with hydrocortisone or prednisone after they collapsed, with little or no appreciable effect. One of those who died quickly had received prednisone for 36 hours before her terminal collapse. Four of the 13 children had convulsions—one as a prelude to terminal collapse and the others between collapse and death.

Gradual Deterioration.—Four children with bacterial pneumonia (Cases 2, 4, 5, and 6) became progressively more ill after admission and died without any notable terminal features to their illnesses. However, one of them (Case 4) was in a collapsed state when admitted six hours before she died, and may have been so as the result of a sudden episode. Finally, the child with mongolism and a large ventricular septal defect (Case 12) reached hospital moribund, with a rectal temperature of 108° F. (42.2° C.) and extensive bilateral pneumonia. He died two hours later.

Seasonal Incidence

Table III shows that most of the deaths occurred during the winter months, and that nearly all of those not attributable to bacteria occurred at times when bronchiolitis is commonest in this community (Elderkin *et al.*, 1965) and when R.S.V. was widely distributed, as judged by the frequency with which we isolated it from children with respiratory tract infections who were admitted to hospitals in this city.

Discussion

It is clearly necessary to be cautious when drawing conclusions from the findings presented here. As we have said, these 22 children are not representative of all who die while suffering from respiratory tract infections; and there are obvious limitations to a discussion of treatment which is based solely on data about fatal cases. However, despite these reservations a number of important facts and indications can be discerned among our findings.

Congenital Abnormalities

Nine of the 22 children had major congenital abnormalities, which probably helped to determine the fatal outcome in each case. Of the five children with congenital heart abnormalities, one (Case 10) died mainly as a result of congestive cardiac failure, one (Case 15) from cardiac arrest during bronchoscopy, and two (Cases 21 and 22) from sudden collapse for which their relatively mild respiratory tract infections did not provide sufficient explanation; the fifth child had extensive bilateral

* Case 3 (*H. influenzae* and R.S.V.) is recorded in both lines.

pneumonia, but his large ventricular septal defect must have added to his respiratory distress. Pulmonary mucoviscidosis commonly leads, as in two cases in this series, to a prolonged and ultimately unsuccessful fight against bacterial superinfection. Congenital facial haemangiomas were probably the portal of entry of the streptococci which killed one child. Lobectomy for congenital emphysema, even when carried out in infancy, leads to permanent impairment of vital capacity, and presumably also of ability to survive serious pulmonary infection (DeMuth and Sloan, 1966).

The frequent association of congenital abnormalities with death during respiratory tract infection in early childhood was noted in a previous report from Newcastle (Elderkin *et al.*, 1965) and has also been found by G. A. Neligan (personal communication, 1967) in follow-up studies of 13,430 single legitimate live births occurring in Newcastle during 1960–2. Of these children, 108 died between the ages of 1 month and 1 year, and of those who came to necropsy 18 were found to have had respiratory tract infections at the time of death, with associated major congenital abnormalities in five cases.

There is nothing original about the observation that children with congenital abnormalities, particularly those of heart or lungs, have a reduced chance of surviving respiratory tract infections; but the high proportion of children with such abnormalities in these series of fatal cases is noteworthy, and helps to explain why respiratory tract infections continue to have a relatively high mortality rate among young children.

Pathogenic Organisms

Only 6 of the 22 deaths in our series were demonstrably attributable to bacterial infections; one other child died from an unexplained complication of a pneumonia probably caused by staphylococci. The pneumococcus, principal agent of fatal respiratory tract infections in pre-antibiotic days, apparently played no part in our series. Our failure to find possible bacterial causes for the illnesses of 15 of the 22 children is all the more significant because only four of them had received antibiotics before coming to hospital. Furthermore, in many cases we were able to culture heart blood and lung aspirate collected a few minutes after death, and we think it unlikely that bacteria responsible for fatal pulmonary infections would commonly escape detection by such means.

R.S.V. was isolated from 3 of the 11 children from whom appropriate upper respiratory tract swabs were collected during life, and from necropsy lung tissue of 8 out of 21 children. The first of these findings can be compared with figures from a survey of our own, to be published in more detail elsewhere, in which we isolated R.S.V. from the upper respiratory tract swabs of only 4 out of 295 children admitted to hospital with no clinical respiratory tract infection; but we have no information about the frequency with which this virus can be isolated from the lungs of children who die from non-respiratory causes. The significance of our high rate of isolation of R.S.V. from the 22 fatal cases is enhanced by the fact that we isolated no other viruses from their respiratory tracts, despite the wide range of culture procedures used. It is of interest that we isolated R.S.V. from the lungs of all four children who died of non-bacterial pneumonia, but from the lungs of only three of the nine who died of bronchiolitis. The latter condition is known to be predominantly due to R.S.V., in Newcastle (Elderkin *et al.*, 1965) as elsewhere (Chanock *et al.*, 1961; Beem *et al.*, 1962), and though we do not know of conclusive evidence that it is also the predominant cause of fatal bronchiolitis, it seems likely that this is so. A possible explanation of our findings is that R.S.V. survives better in pneumonic lung than in bronchiolitic lung after the death of the patient, but there are many other possibilities.

R.S.V. infection was the presumptive cause of death in four cases of pneumonia and in three cases of bronchiolitis, and was

found in the upper respiratory tract of one other child who died with only minor pathological changes in his respiratory tract. The isolation of R.S.V. as well as *H. influenzae* type b from the respiratory tract of the child with epiglottitis may have been coincidental; but since pathogenic collaboration between viruses and this bacterial species has been postulated in various conditions and demonstrated in some (see Turk and May, 1967), the suggestion that R.S.V. plays a part in the aetiology of haemophilus epiglottitis cannot be dismissed out of hand.

Speed of Diagnosis and Treatment

Several of the children were desperately ill before they reached hospital, and in some cases before any medical help was sought. Of the two who died of staphylococcal pneumonia, one might have survived if she had received a more appropriate antibiotic than tetracycline during the early days of her illness, and the other if he had come under medical care before he had been ill for a week. Haemophilus epiglottitis is virtually always a necropsy diagnosis in Britain (Jones and Camps, 1957; Johnstone and Lawy, 1967), but in those parts of the U.S.A. where the condition is well known, promptly diagnosed, and treated by immediate tracheotomy and administration of appropriate antibiotics the recovery rate is high (Berenberg and Kevy, 1958). We suspect that more young children die of haemophilus epiglottitis in this country than the number of recognized and reported cases indicates, and that prompt recognition and treatment might save quite a number of lives. However, the one child with this condition in our series was moribund within about half an hour of being found in a state of severe respiratory distress, and his life could have been saved only by remarkably rapid and well-informed action. The fulminating course of the case of streptococcal septicaemia and pneumonia also left very little time for diagnosis and treatment, especially as there were no strong clinical indications of the nature of the infecting organism. It is impossible to assess the extent to which earlier diagnosis and treatment might have improved the prognosis of any of the children whose infections were apparently not bacterial.

Antibiotic Treatment

Apart from the suggestions made in the preceding paragraph it does not appear that better use of existing antimicrobial drugs would have prevented the deaths of any of the children in this series; but it seems likely that if effective antiviral agents become available there may be a further considerable fall in the mortality rate of respiratory tract infections in early childhood.

Other Forms of Management

Sudden and substantially irreversible collapse was a prominent clinical feature of the illnesses of many of these children, as it was in many of the cases of bronchiolitis reported by Hubble and Osborn (1941) and by Disney *et al.* (1960). The mechanisms underlying such collapse are obscure, and we do not know what parts dehydration and hypoxia play in its production. Some of the children in our series were given intravenous fluids and all received oxygen, but hardly any biochemical investigations were carried out to determine the extent of their need for such treatments and the adequacy of the measures employed. Morrison (1955) showed that oxygen tents, as commonly used, may fail to supply enough oxygen to children with acute respiratory tract infections. Simpson and Flenley (1967) confirmed that administration of 40% oxygen cannot be relied upon to produce normal levels of arterial oxygen tension in such cases; they also showed that clinical signs of respiratory distress are not to be trusted as indices of blood-gas levels, and that uncorrected respiratory acidosis in such

children carries a poor prognosis. Their work thus suggests that repeated direct measurements of arterial blood-gas and pH levels might do much to improve the management of children with severe respiratory tract infections; we would add that repeated electrolyte determinations might also be of value. The use of modern microtechniques greatly reduces the extent to which such investigations disturb a sick child. The mortality rate associated with respiratory tract infections in childhood seems more likely to be reducible by such an approach than by any other at present available to us.

Summary

Of 22 children with respiratory tract infections who died in Newcastle and Durham hospitals during a 27-month period, 19 were less than 1 year old. Nine had major congenital abnormalities. Bacterial infections were apparently responsible for only 6 of the 22 deaths. Respiratory syncytial virus was the only potential pathogen isolated from eight of the children; it was isolated from necropsy lung specimens in seven of these cases, including all four cases of pneumonia with no apparent bacterial cause; and it was also isolated from the upper respiratory tract and the lung of a child with haemophilus epiglottitis. No other viruses were incriminated in any of the 22 cases. Sudden and substantially irreversible collapse was a common feature, especially in the cases not apparently caused by bacteria. Investigation of the blood-gas levels and

biochemical changes in such children is suggested as the most promising approach to improved management.

We gratefully acknowledge the use of clinical notes and reports by numerous colleagues at the Royal Victoria Infirmary (11 cases), Newcastle General Hospital and Dryburn Hospital, Durham (five cases each), and Walker Gate Hospital, Newcastle (one case); also of necropsy reports on the five Dryburn Hospital patients by Dr. J. E. Ennis and on eight of the infirmary patients by Drs. T. Ashcroft, C. Ashton, A. R. Morley, and A. Talerman; and of histological sections of the lungs from all these patients. We are indebted to many of our laboratory colleagues for technical assistance, and also to the Scientific and Research Subcommittee of the United Newcastle upon Tyne Hospitals for their continued support. During this work one of us (M. D. H.) held a research grant from the Medical Research Council.

Further Experience of Reactions, Especially of a Cerebral Nature, in Conjunction with Triple Vaccination: A Study Based on Vaccinations in Sweden 1959-65

JUSTUS STRÖM,* M.D.

Brit. med. J., 1967, **4**, 320-323

The previous report concerning reactions in conjunction with triple vaccination in Sweden during the period 1954-8 (Ström, 1960) aroused considerable attention and also criticism (Malmgren *et al.*, 1960; Hellström, 1962). To question the propriety of recommending universal vaccination against whooping-cough in all circumstances and in all countries was naturally a serious matter. Even if the predominant view is still that pertussis vaccination is of such value that it should be universally recommended, certain authorities (Wilson and Miles, 1964; Herrlich, 1965; Ehrengut, 1966) express some doubt on the point.

However, one absolute requirement must be that the complications occurring in connexion with vaccination are carefully observed and recorded. It is also important to note whether in due course the incidence or the severity of the side-effects is reduced. A further requirement is to ascertain whether the complications that may occur are likely to affect the incidence and fulfilment of vaccination.

Material.—A study was made of children under the control of child welfare clinics. Every vaccination clinic was sent an annual questionnaire for notification of reactions that had occurred. All children's hospitals in the country were asked to report annually concerning treated cases of postvaccinal complications. For the years 1962-4, furthermore, special reports were requested from the welfare clinics on whether vaccination had been carried out.

Results

Table I shows the various types of cerebral reactions observed. Of the 167 cases 81 were admitted to hospital.

TABLE I.—Cerebral Reactions in Conjunction with Triple Vaccinations 1959-65

Year	Cerebral Injury	Convulsions	Hypsarrhythmia	Shock	Irritability + Abnormal Spinal Fluid	Abnormal Screaming	Total
1959	1	7	1	3		4	16
1960		5	1	7		3	16
1961		12		3		1	16
1962	1	12		5		1	19
1963		9	2	9		1	21
1964	1	11		11		4	27
1965		24		16	2	10	52
	3	80	4	54	2	24	167

Cerebral injury was thus reported in three cases, which are described in some detail.

Case 1.—The child was said to have developed normally. The first injection was given at the age of 5 months. The patient was febrile for two to three days, and for one week was very drowsy. The second injection, given six weeks later, produced the same reaction, but the child then became extremely listless, "did not react to anything," and convulsive attacks started one week after the injection. The attacks increased in frequency and duration and were followed by rapid mental regression. E.E.G. showed great paroxysmal activity. While the child was in hospital, at 7 months

* Hospital for Infectious Diseases, Stockholm, Sweden

of age, decerebrate, rigidity was diagnosed, and encephalography revealed cerebral atrophy. Toxoplasmosis and Wassermann reactions were negative.

Case 2.—This child was healthy and of normal development. There was no reaction after the first injection. The patient had a convulsive attack, and a temperature of 39.5° C. on the ninth day after the second injection at the age of 7 months. Next day there was a new attack—clonic on the right side—followed by paralysis. Lumbar puncture revealed albumin 34 mg./100 ml. and 2 cells. On the following day there were similar convulsions and paralysis, and complete loss of contact. E.E.G. showed incessant paroxysmal activity over the entire left hemisphere. Increasingly severe convulsions occurred. The child was afebrile after three weeks, when a stage of complete decerebration developed. A special examination showed a heavy transient rise of total protein in the cerebrospinal fluid and a rise of the gammaglobulin fraction in blood and fluid. Culture for bacteria was negative. No virus was found in nasopharyngeal secretion, cerebrospinal fluid, or faeces. The senior physician expressed his suspicion of a direct relation to triple vaccination, and the National Bacteriological Laboratory declared that "vaccination as an aetiological factor could not be excluded."

Case 3.—This child, birth weight 2,840 g., had a normal birth and normal psychomotor development. The second injection was given at 4½ months of age. Four hours after the injection the child had a convulsive attack lasting a few seconds in the left half of the face and arms, followed by flaccidity in the left arm and leg, and slightly, too, in the right arm; was not unconscious, and was taken to hospital with a temperature of 38.2° C., but otherwise unaffected. Convulsions returned six weeks later, starting in the right half of the face and in the right arm and leg. After half an hour convulsions followed in the left side. A similar attack occurred on two other occasions. After a severe attack at 11 months of age the child was admitted to hospital. Wassermann reaction and toxoplasmosis were negative. E.E.G. showed grave abnormality. Encephalography revealed cortical and central atrophy on the right side. Later there was considerable regression in development.

Convulsions and Shock.—Clonic convulsions alone occurred in 80 cases. Certain remarkable states of persistent tonic cramp also seem to occur at times. The shock (54 cases) is characterized chiefly by a sudden loss of consciousness lasting for a few minutes up to half an hour, accompanied by flaccidity and pallor or cyanosis, or both.

Reaction and Ordinal Number of Injection.—Convulsions occurred in 42 cases after the first injection, in 28 after the second, and in 9 after the third (in one case after a fourth), and shock in 34 cases after the first, 19 after the second, and 1 after the third. Thus most cases occurred after the first injection.

Time interval between injection and reaction is shown in Table II (data are lacking in 20 cases of convulsions and two of shock). The reaction usually came on during the first day, and in most cases in the first six hours. Two cases of convulsions, however, occurred on the second day, one case on the sixth, and one on the seventh. As regards the two latter, it may be mentioned that one child had a temperature of 39° C. for a whole week, which was followed by convulsions, at first seven or eight a day, then diminishing in frequency and ceasing after a month. The second child had a convulsive attack without fever on the sixth day after the first injection. The convulsions returned five hours after the second injection, with a temperature of 38.1° C. Convulsions were observed on two other occasions later in the year. In two of the cases of cerebral injury the convulsions also came late. Repeated convulsive attacks were described in some other children. An example was a child who had convulsions six hours after the injection. An hour later they returned, accompanied by a temperature of 38.1° C. Three days later there were renewed attacks, the temperature being 37.4° C. Another child had convulsions

TABLE II.—Time Interval Between Injection and Reaction

Type of Reaction	Hours after Injection				Day after Injection		
	0-3	4-6	7-12	13-24	2nd	6th	7th
Convulsions	17	18	9	12	2	1	1
Shock	34	14	2	2	0		

one hour after the vaccination, again after seven hours, four times during the following night, and seven times on the next day.

Temperature at Time of Reaction.—The temperature was reported in only 26 cases of convulsions and 11 of shock (Table III). Fever was not always present. In 9 out of 26 cases of convulsions and in 6 out of 11 cases of shock the temperature was not above 38° C.

TABLE III.—Body Temperature at Onset of the Reaction

Type of Reaction	Temperature (°C.)						
	-37.4	37.5-38	38.1-38.5	38.6-39	39.1-39.5	39.6-40	> 40
Convulsions	5	4	3	8	2	3	1
Shock	3	3	2	3			

Hypsarhythmia was reported in two children two to three days after the vaccination and in two others after a week.

Persistent uncontrollable screaming was included only if the state lasted for more than 12 hours or necessitated admission to hospital.

Meningeal Involvement.—Lumbar puncture was performed in nine children who had convulsions: in six the findings were normal and in three abnormal. The latter cases were also clinically more severe. Twenty-four hours after the injection one child had a general attack, which recurred several times during the following week. The cerebrospinal fluid showed 9 cells. The second child was very irritable on the day of injection, had diarrhoea on the second day and a temperature of 37.8° C., and on the third day had convulsions and a temperature of 39.4° C. These symptoms recurred on the fourth day and for a time the child was in a moribund state (tachycardia, bigeminy, enlarged heart). Cerebrospinal fluid showed: P+, N+, 12 cells. The third child had fever on the day after the vaccination, thereafter vomiting for several days, and again fever, 38-39° C. with convulsions. Lumbar puncture showed 28 cells. Lumbar punctures were performed in four of the shock cases. In two the findings were normal, one had a borderline cell content (5 cells/cu. mm.), and one had a high protein level (81 mg./100 ml.) In the latter case the shock condition recurred once. Of special interest are two patients who clinically showed only very moderate irritability but nevertheless a distinct meningeal involvement. In one case the child was whiny and irritable on the day of injection and had a temperature of 39° C. The next day the temperature was 40.1° C. and the fontanelle was bulging. Lumbar puncture showed 30 cells. The other child was also moderately irritable and the lumbar puncture showed 57 cells. In all, therefore, six children on whom lumbar puncture was performed showed signs of meningeal involvement.

The incidence of cerebral reactions is shown in Table IV. Reaction in the form of convulsions, shock, and meningeal involvement occurred in 1:3,600 vaccinated children (convulsions 1:6,500, shock 1:9,500). Including abnormal screaming the incidence is 1:3,100.

Other Reactions

High temperature has been reported annually in 50 to 150 cases. A temperature above 40° C. is not unusual, the record being 42° C.

TABLE IV.—Incidence of Cerebral Reactions After Triple Vaccination 1959-65. (Cases of Abnormal Screaming Not Included)

Year	No. of Vaccinees	Cerebral Reactions	Incidence
1959	63,141	12	1:5,300
1960	55,042	13	1:4,200
1961	64,226	15	1:4,300
1962	68,225	18	1:3,800
1963	76,361	20	1:3,800
1964	90,697	23	1:3,900
1965	98,584	42	1:2,300
	516,276	143	1:3,600

One child had a temperature of 40° C. for three days, and the next injection, with only one-tenth of the previous dose, produced the same reaction.

In recent years rashes have been reported in 15 to 20 cases annually. *Exanthema* of a morbilliform character or *erythema* appears to be most common. The same kind of morbilliform exanthema of 48 hours' duration appeared in two children after both the first and the second injection. *Oedema* of the face, hands, and feet, accompanied or unaccompanied by erythema, has been observed. In 29 cases on which detailed reports were made the exanthema occurred in 15 cases after the first injection, in 11 after the second, and in three after the third; and in respect of time, in 19 of 27 cases on the first day, in six on the second, and in one case each on the third and fourth days.

Local skin reactions, particularly in the form of sterile abscesses, were very common up to 1963, but have since become rare, as aluminium has been eliminated from the vaccine.

Gastrointestinal symptoms were occasionally reported. Vomiting and diarrhoea occurred after a day or so, lasting for a couple of days to roughly a week. Repeated injections produced the same effect.

Incidence and Fulfilment of Triple Vaccination

Special reports were requested for children born in 1962-4. Figures were obtained concerning 208,186 children (out of a total of 235,283—that is, 88.4%). Of this number 156,802 (75.3%) had been completely vaccinated, 17,342 (8.3%) incompletely, and 34,042 (16.4%) not at all.

The reasons for non-vaccination or incomplete vaccination are given in Table V. The reason for non-vaccination in over half of the cases was the parents' refusal. This corresponds to 8.6% of the total number of children. Medical reasons were reported in only 5.2%—that is, about 1%. Incomplete vaccination would seem to be due chiefly to a reaction to earlier injection. Medical reasons and parents' refusal were the cause of interrupted vaccination in roughly equal numbers of cases—1.4 and 1.5% respectively, together representing about 3%. This figure is naturally a minimum, as the "unknown" group undoubtedly contains some cases attributable to these two causes. The "other cause" group includes mostly children who had moved or were no longer brought in for control, etc.

TABLE V.—Reasons for Non-vaccination and Incomplete Vaccination

Vaccination	Medical Cause	Parents' Refusal	Other Cause	Unknown Cause	Diphtheria-Tetanus Vaccination Instead
Not done (%) ..	5.2	52.7	10.9	27.5	3.7
Incomplete (%) ..	17.1	18.3	33.4	30.7	0.5

Discussion

The first question on which the material presented throws some light is the classification of the cerebral reactions as serious or negligible. As a rule, naturally the main emphasis was on encephalopathies, which caused serious injury; while convulsions, for example, were regarded as a simple febrile reaction. This may be so in some cases, but the present study shows that in nine out of 26 cases the temperature was normal or at most 38° C. Furthermore, pleocytosis was found in the cerebrospinal fluid of three out of nine children on whom lumbar puncture was performed. In several cases, too, there was a marked tendency towards repeated convulsive attacks, contrary to the usual situation in febrile convulsions.

Provocation of hypsarrhythmia was observed in four cases. Similar observations have been made by others (Baird and Borofsky, 1957; Chao *et al.*, 1957; Bower and Jeavons, 1960; Kringelbach and Sensius, 1965).

Shock appears to be still less dependent on the temperature. In six out of 11 cases this was normal or at most 38° C. In one of the four cases in which lumbar puncture was performed the protein content of the cerebrospinal fluid was raised; another case was on the borderline of pleocytosis.

In two children with relatively mild irritability the cerebrospinal fluid findings were distinctly abnormal. It would be of value to know the situation as regards abnormal screaming, which is not so unusual, and which, because of its intensity and difficulty of appeasement, gives the impression of being of cerebral origin (Hopper, 1961).

With these facts in mind it may be asserted that the convulsions, shock, and abnormal irritability observed after triple vaccination cannot always be regarded as commonplace general symptoms but reflect an objectively demonstrable cerebral reaction. The provocation of hypsarrhythmia supports this view. This is a rather more serious aspect of the problem, and the dividing line between what should and should not be regarded as a severe reaction becomes more fluid. Happily, in the short-term view at least, these reactions appear to have a favourable prognosis.

Pathogenetically the endotoxin of the pertussis bacteria—a well-known neurotoxic agent—must be the factor responsible for the cerebral reactions. The fact that most reactions occur after the first injection is against an allergic origin. Certain observations, however, show a quicker and more severe effect of subsequent injections.

Other observed reactions, such as erythema, exanthema, oedema, and gastrointestinal symptoms, also have a rapid onset, usually after the first injection. But there must be an individual predisposition as well, as it was repeatedly found that the same symptoms recurred after subsequent injections.

To sum up, the vaccination reactions may be regarded chiefly as manifestations of a toxic effect, an individual predisposition being of some significance. The allergic element, on the other hand, appears to fall into the background.

As regards the incidence of different reactions to vaccination, the study shows, for children born during 1962-4, that in at least 3% the side-effects were so serious that further vaccinations were not given. In respect of neurological symptoms there seems to be a tendency to an increase compared with my previous report, in which the incidence was 1:6,000 as against the present 1:3,600—uncontrollable screaming excepted. This is probably only an apparent increase due to keener observation on the part of the medical staff. Only three cases of destructive encephalopathy have occurred in these seven years (1:170,000) as against the figure of 1:50,000-60,000 established by the Board of Health (Malmgren *et al.*, 1960) after the earlier study.

If one further differentiates the present material another group with rather more marked symptoms is distinguishable—that is, the cases in which there was serous meningitis and/or a pronounced tendency to repeated attacks of convulsions, or provocation of hypsarrhythmia, altogether 15 cases. The incidence of these reactions is 1:34,000 vaccinees; the remaining cases—that is, the milder, quickly passing reactions—number 125 (1:4,000).

Finally, a general reflection. It may be seen that reactions following triple vaccination are unusually numerous in Sweden compared with other countries. But it must be remembered that our figures are based on very thorough centralized supervision, to which there is hardly any counterpart in other countries. Only by means of annual reports from all vaccinating bodies in a standardized form can a reasonably clear picture be gained. Experience shows that a general recording duty for physicians in fact results in reports of only a few reactions. This it is extremely important to note in times when vaccinations are increasing every day, and, through the action of our health authorities, tend to become a routine and to be virtually compulsory. The more this happens the more necessary it is to maintain a check on the side-effects, especially in combating

diseases which, with rising standards of hygiene and public services, are in themselves assuming milder forms (Ström, 1960, 1967).

Summary

Among 516,276 triple-vaccinated children in Sweden from 1959 to 1965 neurological reactions to the vaccination occurred in 167 cases—destructive encephalopathy 3, convulsions 80, hypsarrhythmia 4, shock 54, uncontrollable screaming 24, serous meningitis 2. Serous meningitis was also found in three out of nine examined cases of convulsions, and elevated protein in cerebrospinal fluid in one out of four examined cases of shock. Apart from these objective signs of meningeal involvement in certain cases, the study shows that in conjunction with both convulsions and shock there may be no or very little rise of temperature. The convulsive symptoms therefore cannot be classified as a matter of course as simple febrile convulsions.

The incidence of neurological reactions was 1:3,600 vaccinated children (1:3,100 if cases of persistent uncontrollable screaming are included), a rise in relation to the figure of 1:6,000 reported in a study from the years 1954 to 1958. The rise is probably merely apparent, however, owing to the more watchful eye that is kept on these conditions. The more severe reactions leading to permanent injury seem to have decreased.

Analysis of the vaccinations of 208,186 children showed that 75.3% had been completely vaccinated. The figure for the non-vaccinated was 16.4%, rather more than half of them due

to the parents' refusal. Vaccination had not been completed in 8.3%; in at least 3% the reason was probably the severe reaction to a preceding vaccination.

Apart from neurological reactions, erythema, exanthema, oedema, and gastrointestinal symptoms have also been reported. The great majority of reactions occurred after the first injection. Repeated injection appeared to produce the same reaction.

All forms of reaction can be explained as being of toxic origin. An allergic mechanism would appear to be of relatively limited significance; a certain individual predisposition, however, seems to be a factor to reckon with.

Finally, it is emphasized that when nation-wide vaccination is recommended detailed information should be required concerning postvaccinal reactions, as is done in Sweden in conjunction with triple vaccination.

Survival of Burkitt's Lymphoma Patients in Mulago Hospital, Uganda

R. H. MORROW,* M.D.; M. C. PIKE,† PH.D.; A. KISUULE‡

Brit. med. J., 1967, **4**, 323–327

Although much work has been done on clinical aspects of Burkitt's lymphoma, and intense interest has been shown in the relatively high rate of remissions and even "cures" among patients with this disease, there has been little analysis of long-term survival. The major reason for this has been the apparently enormous and seemingly insurmountable problems of keeping track of patients in the developing countries of Africa.

Clifford, working in Kenyatta National Hospital, Nairobi, Kenya, has been able to circumvent this problem to a very large extent by keeping patients in hospital for extended periods, and to date his series (Clifford, 1966; Pike, 1966) is the only major one in which complete survival information on the vast majority of patients is available.

Ideas on survival of patients attending Mulago Hospital, Kampala, Uganda, have been based on those known to have died plus those who continued to return to the follow-up clinic, but the fate of upwards of 50% of the patients leaving the hospital has not been known (Burkitt *et al.*, 1965; Burkitt, 1966). However, by combining the data gathered by Mr. D. Burkitt and Mr. A. Lubega (the Kampala Cancer Registry

social worker) with the data we have ourselves collected since November 1966 it has been possible to obtain survival information on 74 of the 80¹ patients in a defined subpopulation of cases attending Mulago Hospital. This paper reports our findings in this group.

Clinical Material

The present study comprises the 80 patients diagnosed (microscopically, clinically, or at necropsy) as having Burkitt's lymphoma, who presented for the first time at Mulago Hospital between 1 January 1961 and 31 December 1965, and whose place of residence at onset date was in East or West Mengo Districts of Uganda (as demarcated on the last Ugandan Census in 1959²).

The East and West Mengo Districts, with a population of approximately 1½ million, comprise an area around Kampala with a radius of about 110 km. (70 miles). To have extended the follow-up to include further districts of Uganda would have provided rapidly diminishing returns for the extra effort and expense involved.

† Member of the M.R.C. Statistical Research Unit, 115 Gower Street, London W.C.1, on secondment to the Department of Pathology, Makerere Medical School.

‡ Medical Assistant. Employed by Dr. Morrow under the U.S. National Cancer Institute (N.I.H.) Contract No. PH-43-67-47.

An early draft of this paper was read at the East African Medical Research Council's Conference on "Cancer in Africa" which took place in Nairobi, Kenya, from 11–14 January 1967.

¹ A table may be obtained from the authors giving for each of the 80 patients: reference number, age, sex, date of presentation at Mulago Hospital, length of history at that date, tumour involvement at presentation, staging of the disease, if and when microscopically proved, if and when treatment started and what it was (though not the dose, as this was too often unknowable from the notes), date last seen, and condition, length of survival, dates of discharge "improved," dates of recurrences after discharge improved, sites of recurrences, and therapy given.

² East African Statistical Department, Nairobi/Entebbe, 1960.

We considered only patients presenting on or after 1 January 1961. It was about this time that "adequate" chemotherapy became available, and the criteria for diagnosis of the tumour had become relatively clear. The difficulties of tracing patients (and finding their notes) increase greatly with time after discharge, and though restricting ourselves in this way we still had a sufficient number of cases to make analysis instructive, while standing a good chance of finding the necessary high proportion of patients to make analysis valid. We did not consider patients presenting after 31 December 1965, because there had not been a sufficient lapse of time to make analysis of their survival very meaningful.

Of the 80 patients in the defined population at the beginning of this study (early November 1966) 36 had died in the hospital and another three were reliably reported to have died at home, while seven were known to be alive. Of the remaining 34, 11 had been unimproved by treatment and were thought to be dying on discharge, and 22 had been "successfully" treated but had not been seen since discharge. We were unable to find the hospital notes of the remaining patient, Case K229, though we were able to ascertain that she had been discharged. Thus of the 44 patients discharged from the hospital, the fate of 34 was in doubt. One of us (A.K.) devoted three months to tracing these patients. Four were found alive and free from tumour,³ the deaths of 22 patients were confirmed, and indirect evidence of the deaths of two was obtained. No information was forthcoming on the remaining six: three of these had been discharged improved, two had been discharged dying, and one was Case K229 mentioned above (this patient was not considered further here). The position is summarized in Table I.

TABLE I.—Information on Survival Status

	At Start of Study, 1 Nov., 1966	At Analysis, 1 April, 1967
Died in Mulago	36	36
" at home	3	27
Alive	7	11
Lost	34	6
Total	80	80

The diagnosis in 10 patients was made on clinical grounds alone: in two a clinical diagnosis was later confirmed at necropsy. Thus there was microscopical proof of diagnosis in 69 of the 79 patients. In all but one of these 10 not microscopically proved cases the patients are known to be dead. The other patient was improved by therapy but had extensive disease at discharge, and we have not been able to trace him. All "long-term" survivors had Burkitt's lymphoma diagnosed microscopically.

Of the 79 patients, 24 received no specific anticancer therapy. Seven of them were first diagnosed at necropsy; 10 died before diagnosis was confirmed or treatment started; five died during an operative or diagnostic procedure; and two refused treatment—one with far-advanced disease was removed by his parents before biopsy or treatment and died at home the same day; the other (Case J152), a 9-year-old boy with all four quadrants of the jaw involved, was taken home by his parents after biopsy but before treatment. His parents stated that they then took him to the local traditional medical practitioner, after which he had a full remission, but the disease later recurred and he died 385 days after his initial presentation at Mulago. The remaining 55 patients had specific treatment for their disease.

All of these treated patients received some form of chemotherapy. The most frequently used first drug was cyclo-

phosphamide, usually given intravenously but quite often orally and under varying dose schedules—most commonly a single dose, and the vast majority no more than two doses, of 40 mg./kg. body weight intravenously. Other drugs used were mercaptopurine, nitrogen mustard, methotrexate, and vincristine. These drugs were often given in combination, and for recurrences the drugs were usually given in turn if no response was being obtained. Seven patients had fairly extensive surgical excision of their tumour—five bilateral ovariectomies, one bilateral orchiectomy, and one abdominal mass removed.

Survival Time

We have counted survival time from the date of presentation at Mulago Hospital. This date was always easy to establish, and for the purpose of this paper may be regarded as that on which treatment began, a date that was not always completely clear from the hospital notes we managed to find.

For the purpose of the survival curve analysis the three "lost" patients who were discharged to die are assumed to have died on the day they left hospital, but for the two lost patients discharged improved we assume nothing further than that they were alive when they left hospital.

Staging of the Extent of the Tumour

Burkitt *et al.* (1965) have pointed out that the initial response of lymphoma cases in Mulago Hospital to chemotherapy was in part determined by the size of the tumour mass, and from a preliminary look at the survival data it was evident that the extent of tumour involvement was a critical factor in long-term prognosis. In our analysis we finally settled on the following crude division of cases into three categories, similar to those used in the staging of Hodgkin's disease:

Stage 1: Lymphoma limited to one anatomic region or to two contiguous anatomic regions on the same side of the diaphragm.

Stage 2: Lymphoma in two or more non-contiguous or more than two contiguous regions on the same side of the diaphragm.

Stage 3: Lymphoma involving any intrathoracic, intra-abdominal, or intracranial areas, or bone marrow, or more extensive involvement than stage 1 or stage 2.

For example, involvement of both mandible and maxilla on one side of the face is classified as stage 2, whereas involvement of the maxilla and orbit on one side is classified as stage 1.

The major classification problem was whether liver or spleen enlargement constitutes tumour involvement in the absence of a laparotomy or needle biopsy—for this paper involvement was assumed only when there was a positive statement in the notes to this effect.

Results

Table II gives the survival times of the patients who received specific anticancer therapy. Fig. 1 shows the actuarially calculated survival curve for all these 55 cases. This curve

‡ Discharged "improved," not traced. § Discharged unimproved, not traced.

³ One of these patients (Case K76) was not actually seen, but the patient's father and the local chief stated that he was alive and well. The area near his home was particularly disturbed during the "troubles" of 1966 and the patient was alleged to have been afraid to show himself owing to misgivings concerning the reasons for our visits (we attempted to see him on four different occasions). We have no reason to doubt the truth of these statements, and we have accepted them at their face value.

has the same general shape as the graph that was constructed from Clifford's data (Pike, 1966), with the characteristic, striking, long right-hand tail. Patients falling into this tail we regard as "long-term" survivors; all of them have been clinically free from disease for at least 496 days, while the longest remission in a patient who has subsequently died is 382 days—this is the patient who died 479 days after admission. The point on the "% survivors" axis at which the curve becomes horizontal we call "estimated long-term survival rate," and for the treated cases as a whole it is 21%.

FIG. 1.—Survival curve for all 55 treated cases.

The most important determinant of survival in this series appears to be the extent of the disease on first admission (see Fig. 2 and Table III). The single stage 1 treated patient who has not survived was a 9-year-old girl who presented with a large tumour of the left thigh. This child died in the hospital two weeks after admission with an apparently fast-extending tumour, but it is not clear from the hospital notes why she died so soon and why necropsy was not performed. There is a suggestion on the histology request form that she might have had more extensive tumour involvement, and hence might not have been a stage 1 case.

FIG. 2.—Survival times in Stages 1-3.

TABLE III.—"Long-term" Survival and Stage of Disease at Presentation

2	10	3	28
3	34	3	8
All patients	50	11	21

* Excludes "lost" patients.

† Actuarially calculated (see Figs. 1 and 2).

Younger patients did better than older patients (see Fig. 3). However, the age of the patient and the extent of his disease at presentation are highly interrelated (see Table II), and it is not possible with this limited number of cases to separate them completely satisfactorily. Fig. 4 shows that among stage 3 cases age is apparently irrelevant, though there is a hint of better prognosis for the younger patients with stage 2 disease. If attention is restricted to patients under 10 years of age it is clear from Table II that the stage of the disease remains of paramount importance.

FIG. 3.—Survival times of patients according to age.

No relation exists—within a staging division—between length of history and prognosis.

FIG. 4.—Survival times in stage 3 patients according to age.

It would clearly be extremely useful if on the basis of this series we could make some assessment of the relative efficacy of different chemotherapeutic regimens. However, as the extent of the disease at presentation appears to have a critical prognostic value, we need to compare different drugs (and different drug schedules) *within a single staging category*. Table IV shows that this is possible only with stage 3 cases; and Fig. 5 shows, within this staging division, the comparison of initial treatment with cyclophosphamide against all other drugs. For the first few months the patients receiving cyclophosphamide do better, but this advantage is not maintained.

TABLE IV.—Initial Chemotherapy

Stage of Disease at Presentation	Drug		
	Cyclophosphamide	Other	Total
1	5	1	6
2	10	1	11
3	25	13	38
All patients	40	15	55

FIG. 5.—Survival times in stage 3 patients according to treatment.

Long-term Survivors

Ten of the 11 long-term survivors were under the age of 7 at presentation; while their sex ratio (seven males, four females) is identical to that of all treated cases.

Two important points arise from a study of the treatment of these 11 patients. The first is the apparent value of surgery in some cases. All three survivors with stage 3 disease had extensive surgical excision of their tumour—two had bilateral ovariectomies and one had a tumour mass that involved the bladder, right ureter, and ileum removed. Though there was possibly abdominal tumour remaining in all three patients, the bulk of it is excised. Two of these patients also had jaw or orbit involvement, but surgical excision was never attempted at these sites. An orchidectomy, first of the right testis and two and a half years later of the left, was performed on one stage 1 survivor (Case K99). Altogether seven patients had surgery with removal of most of the tumour mass, and four of these are long-term survivors.

The second point is that four of the survivors (all stage 1 cases) had recurrences. One of these patients was the testicular tumour case referred to in the previous paragraph. All of the remaining recurrences were in a site clearly different from the original one. These four patients all had complete clinical remissions followed by recurrences from 22 to 80 weeks later. Their recurrences were all still classifiable as stage 1.

Discharged "Improved"

To decide whether a patient has had a full or partial remission, or neither, is difficult in the best of circumstances. It is particularly so when these decisions have to be made retrospectively on the basis of case notes alone. We have nevertheless attempted this, and a certain amount of useful information was obtained.

Mulago Hospital notes invariably stated for each discharged patient whether "improved" or "not improved," and we have accepted this dichotomous definition of remission as the best we could manage—we have thus taken "improved" to mean "in remission" except when the notes also showed that the patient still had "significant" residual tumour (this was not always easy to decide).

Table V shows the discharged improved rate related to the extent of the disease at presentation—this relationship has been reported in a slightly different manner and in further detail as regards extent of remission by Burkitt *et al.* (1965).

TABLE V.—Discharged "Improved" and Stage of Disease at Presentation

Stage	No. of Patients	No. Discharged "Improved"	% Discharged Improved
1	6	5	83
2	11	8	73
3	38	21	55
All patients	55	34	62

Of the 24 patients discharged improved who subsequently had recurrences 10 did not bother to return to Mulago Hospital—two of these were stage 2 and the others stage 3 cases. The length of time between the discharge of these patients and death are (in days): 51, 63, 88, 124, 133, 162, 240, 285, 307, and 391. It is surprising that these patients did not think it worth their while to return, in particular those with lengthy remissions.

Discussion

In this series the stage of the disease at presentation was of critical prognostic importance. However, as is well known to anyone working with this tumour, the disease does not invariably progress from stage 1 through stage 2 to stage 3. In fact, many stage 3 patients present with abdominal lesions alone, and by our definition these cases have been stage 3 throughout the course of their disease. From the histories of the vast majority of the stage 3 cases with both abdominal and jaw lesions it was simply not possible to tell the time sequence of symptoms; and in the few instances where the jaw tumour appeared to have preceded the abdominal involvement one was always doubtful of the true significance of this, since the jaw lesions were so much more obvious. Similarly, though a number of stage 2 patients who later died had progressed to stage 3 before death, so that this sequence seems at least to be possible, we have to bear in mind that the first physical examination might well have missed a small abdominal mass. There are a number of cases in which the abdominal tumour appears to have preceded the jaw lesion.

Surgical reduction of abdominal tumour masses produced our only stage 3 survivors. This result, we feel, lends support to the finding that the critical factor in prognosis is the extent of disease at presentation. The risks attendant on abdominal surgery would therefore appear to be worth taking. This is in accordance with the results obtained in Ibadan, Nigeria (Ngu, 1964), where the only long-term survivors with stage 3 disease had excisions of their abdominal tumours.

Four of the five stage 1 long-term survivors had recurrences. Treatment of recurrences is thus distinctly worth while. In two of the stage 2 deaths the patients had had long remissions before dying at home without returning to Mulago Hospital,

and it is possible that they might have survived if they had returned for further treatment at recurrence.

The results obtained from this series do *not* agree in all respects with the results found by Clifford (1966).

We divided Clifford's patients into our three staging categories on the basis of the details given in his paper, but both the "remission" rate (about 80%) and the long-term survival rate (about 17%) were independent of this division. A possible explanation of this discrepancy is to be found in the different drug dosages used in Nairobi and Kampala.

On average Clifford gives about two to three times the initial dose of drug given at Mulago Hospital. This appears to have resulted in a number of important differences in what we might term secondary response. A number of Clifford's stage 3 patients are long-term survivors on chemotherapy *alone*, a phenomenon not observed in our series. But the recurrence times for tumours of small extent are on the whole much shorter than those observed in Kampala.

There is some evidence, both clinical and experimental (Burchenal and Burkitt, 1967), that host defences may play an important role in survival in Burkitt's lymphoma. Regressions (one in this series, see above) and "cures" have been noted after little or no specific chemotherapy; while Klein and his co-workers have obtained results interpreted as showing a tumour specific component in the sera of Burkitt's lymphoma patients in complete remission. If one adopts this proposition then one may argue that the chemotherapeutic agents used might not only affect tumour tissue but also affect the patients' immune response, and the balance between these two results of therapy might be critical. Clifford is giving a quantity of drug which will destroy the greater percentage of tumours (at least of large ones), but this results in a greater reduction in the patients' own defences—some of his cases die of leukaemia, and the initial drop in the Nairobi survival curve is very steep, so that the end-result is a similar "success" rate in Nairobi and Kampala, but with marked differences in effect of initial tumour location—these arguments in a slightly different form have been previously suggested by Burkitt *et al.* (1965).

This, however, is all very speculative, and the major problems of which drug to give, the best total dose (of a particular drug) to give, and whether this should depend on the "extent" of the disease, remain unresolved. It is our belief that these problems will not be resolved without strictly controlled clinical trials. Joint trials conducted simultaneously in a number of centres, with each of these centres drawing patients from an area as wide as possible, and the maintenance of a complete follow-up, would be of enormous value in getting sufficient numbers of cases together in a short time, and it is hoped that this can be arranged.

This study has shown that successful follow-up of a limited group of young patients, even retrospectively, is possible in Uganda. We attribute our success to having a non-hurried approach, in particular to being willing to spend considerable time explaining what we were doing to people encountered in our searches. After this explanation information was often forthcoming that the informant either denied knowing beforehand or did not bother to remember.

NOTE.—Mr. Clifford has now reviewed his data, employing a system of staging similar to that used here, and reports that he has found some relationship between this method of staging and prognosis. The relationship was not nearly as striking as that found in our series, and we still feel that the factors discussed above are those most likely to account for the difference.

Summary

Follow-up of 80 cases of Burkitt's lymphoma treated in Mulago Hospital, Uganda, has shown that the "long-term"

survival rate is approximately 1 in 5. This rate is markedly dependent on the extent of anatomical involvement of the lymphoma at presentation in this series, but in the previously reported series of Clifford (1966) this is not so. A possible reason for this discrepancy is sought in the different dosages of drugs used in the two centres.

This investigation represents a continuation and extension of the work initiated by Mr. D. Burkitt. We are grateful to Mr. Burkitt and Mr. S. Kyalwazi, who between them treated nearly all the cases reported in this series, for permission to follow up their patients. Special acknowledgement is due to both the past and the present pathologists at Makerere Medical School, and in particular to Dr. D. H. Wright, for carrying out the microscopy of the cases considered in this paper. We would like to thank Mrs.

Barbara Wright (registrar, B.E.C.C.-financed Kampala Cancer Registry) for the assistance she gave us in collecting details of the patients. We gratefully acknowledge the financial support of the U.S. National Cancer Institute (N.I.H.) under their Contract No. PH-43-67-47, and of the British Empire Cancer Campaign for Research.

Hypokalaemic Alkalosis and Hyperplasia of the Juxtaglomerular Apparatus without Hypertension or Oedema*

L. J. BEILIN,† M.D., M.R.C.P.; N. SCHIFFMAN,‡ M.D.; M. CRANE,§ M.D.; D. H. NELSON,||

Brit. med. J., 1967, **4**, 327-331

Hyperaldosteronism is commonly associated with either hypertension and hypokalaemic alkalosis as in renal vascular hypertension, malignant hypertension, and primary aldosteronism, or with oedema as in cirrhosis with ascites, the nephrotic syndrome, and chronic congestive heart failure. A dissociation between the hypertensive, potassium-losing, and continued sodium-retaining effects of aldosterone has previously been noted (Nelson and August, 1959) in patients who become oedematous. Three patients have been described with hypokalaemia, hyperaldosteronism, and hyperplasia of the juxtaglomerular apparatus but without hypertension or oedema (Bartter *et al.*, 1962; Boucher *et al.*, 1964; Ames *et al.*, 1965). The present case, like the other similar cases, apparently represents another instance in which aldosterone in excess has not resulted in hypertension. The cause of the syndrome described in these cases is unknown, but it has been suggested that it represents an important aberration from the normal relations between the renin-angiotensin-aldosterone system and blood pressure control.

Case Report

The patient was an 18-year-old negro male whose illness dates from infancy. He was delivered after a seven-month pregnancy and was well until 4 months of age, when he stopped growing. At 7 months he was admitted to the Children's Medical Center in Dallas, Texas, after two weeks' incessant vomiting. He was found to be grossly dehydrated, wasted, and drowsy. He was in opisthotonos, but Trousseau and Chvostek signs were negative. The testes were undescended and he had a first-degree hypospadias. Investigations at that time revealed a serum bicarbonate of 46 mEq/l., serum chloride 74.6 mEq/l., serum sodium 123 mEq/l., serum potassium 4.8 mEq/l., and a blood pH of 7.65. Idiopathic alkalosis was diagnosed, and he was initially treated with ammonium

chloride, sodium chloride, and deoxycortisone without effect. He eventually recovered after subcutaneous fluids and oral feeding, and was discharged clinically well but with persistent hypochlorhaemic alkalosis.

He grew slowly, walked at 15 months, but at 4 years was noted to have polyuria and polydipsia. He was then reinvestigated and found to have one testis in the scrotum and a bone age of 3½ years. Hypochlorhaemic alkalosis was present with serum chloride of 87 mEq/l., serum bicarbonate 41 mEq/l., a blood pH of 7.59, and a creatinine clearance of 116.6 ml./min. He was given no further treatment at that time.

Fig. 1.—Patient aged 18, with prepubertal genitalia.

‡ Instructor in Medicine, University of Southern California School of Medicine, Los Angeles.

§ National Institutes of Health, Career Development Awardee—9-K3-HE-7627, and Research Professor of Medicine, Loma Linda University, Loma Linda, California.

|| Investigator, Howard Hughes Medical Institute. Present address: University of Utah College of Medicine, Salt Lake City, Utah.

He attended school, requiring special classes, and received no further medical treatment until the age of 17, when he suffered from recurrent dislocation of the patella. At 18 he presented to the endocrine clinic at the Los Angeles County General Hospital complaining of delayed puberty. His only other symptoms were constipation and diminished energy. He denied ingestion of drugs or having diarrhoea, and had no attacks of paralysis or tetany.

Physical examination showed him to be alert, with a eunuchoid build and prepubertal genitalia (Fig. 1). The right testis was in the inguinal canal and was 2 cm. long; the left was in the scrotum and was 3 cm. in length. His height was 159 cm. in the 10–25th percentile and exceeded his span by 2 cm. His weight was 34 kg., which was below the third percentile for his age and height. Blood pressure ranged from 108/60 to 90/50 with no significant postural changes.

Preliminary investigations revealed a serum potassium of 2.6 mEq/l., serum bicarbonate 29 mEq/l., serum chloride 85 mEq/l., serum sodium 134 mEq/l., and blood urea 10 mg./100 ml.; alkaline phosphatase 6.5 and 6 Bodanski units/ml.; and serum magnesium 1.6 mg./100 ml. Serum cholesterol was raised on two occasions to 301 and 256 mg./100 ml. Serum bilirubin was 0.7 mg./100 ml. and bromsulphalein retention less than 5% in 45 minutes. Haemoglobin was 11–13.5 g./100 ml., with a normal film and a W.B.C. of 7,100, and normal differential. Bone age estimated by skeletal x-rays was 15–17 years. Skull and chest x-ray examination showed nothing abnormal. E.E.G. was normal. Buccal smear was negative for Barr bodies. E.C.G. showed changes of hypokalaemia with inverted and biphasic T waves and a prolonged Q–U interval. Urinalysis showed a normal sediment with less than 100 mg. protein per 24 hours and no glucose (tested with Clinistix). Urine cultures were sterile. Creatinine clearance was 98 ml./min. Urine concentrating ability was impaired as shown by urine osmolality of 378 mOsm/l. after four hours' intravenous infusion of pitressin at a rate of 4 microunits/min. Urinary acidification was slightly impaired, the urine reaching a minimum pH of 5.9 after an oral ammonium chloride load of 0.5 g./kg. body weight (Wrong and Davies, 1959). Twenty-four-hour urine amino-acids totalled 179 and 490 mg./100 ml. with no distinctive pattern. An intravenous pyelogram suggested some irregularity of the calices of the right kidney but was otherwise normal. Renal aortogram and ¹³¹I hippuran renal scan were normal. Twenty-four-hour urine 17-ketogenic steroids and 17-ketosteroids were normal and there was a

normal response to intravenous A.C.T.H. and metyrapone. Urinary gonadotropins were less than 6 units and 6–16 units/24 hours on two occasions. P.B.I. was 6.8 µg./100 ml. and a ¹³¹I uptake was 14% in 24 hours, rising to 40% after thyroid-stimulating hormone.

Balance Studies

Metabolic balance studies carried out in the metabolic unit of the Los Angeles County General Hospital were designed to determine the site and cause of potassium loss. Results are shown in Fig. 2. On a potassium intake of 60 mEq/day excretion of urinary potassium exceeded intake, and this urinary potassium loss persisted when dietary potassium was reduced to 20 mEq/day. Total exchangeable potassium at this time was 1,172 mEq compared with an expected normal of 2,000 mEq for a person of his size. When dietary sodium was reduced to 10 mEq/day, urinary potassium excretion fell below intake. Increasing the dietary sodium to 120–150 mEq/day then caused an immediate rise in urine sodium and return of negative potassium balance. These results were interpreted as evidence that the hypokalaemia resulted from renal potassium loss due to hyperaldosteronism, the potassium retention induced by the low sodium diet being due to insufficient sodium reaching the distal tubule to exchange with potassium under the influence of aldosterone. When spironolactone, 200 mg. daily, was administered, urine sodium increased to 140 to 230 mEq/day, potassium was retained, and for the first time the serum potassium rose toward normal (Fig. 2).

Twenty-four-hour urine aldosterone excretion was measured on several different occasions. Table I shows that there was only one elevated value during the initial hospital admission, but that two weeks after cessation of two months' spironolactone therapy values were raised. Aldosterone secretion rate was 231 µg./100 ml., which was a high normal value for adults on 100 mEq sodium diet and is probably high for a prepubertal individual weighing 34 kg.

TABLE I.—24-Hour Urinary Aldosterone Levels

Diet	Lab. A (N 3–32 mg.)	Lab. B (N 5–19 mg.)
60 mEq K	22	—
80 mEq Na	11	—
20 mEq K	6	17.4
	7	14.1
58 mEq Na	57	27.7
	2	—
2 weeks after 2 months of spironolactone	—	44
	—	45

FIG. 2.—Upper graph: Solid line represents serum potassium; the horizontal dotted line indicates the lower limit of normal serum potassium. Middle graph: Solid blocks represent 24-hour urine sodium excretion; the horizontal dotted lines indicate daily sodium intake. Lower graph: Solid blocks represent 24-hour urine potassium excretion; the horizontal dotted lines indicate daily potassium intake. Four main balance periods are shown from left to right. The first two demonstrate a tendency to renal potassium loss in the presence of hypokalaemia. The third period shows potassium retention on a low sodium intake and increased potassium loss when the sodium intake was increased. The fourth period shows potassium retention and natriuresis induced by Aldactone-A (spironolactone) and a rise in serum potassium towards normal.

Plasma Renin Activity

Plasma renin activity was measured¹ by a modified method of Boucher. The patient was studied initially while taking a low-sodium diet, a high-sodium diet, and after a period of spironolactone therapy. Samples were withdrawn after the patient was supine, after an overnight sleep, and again after four hours' standing. Table II shows that the values obtained in the patient were

TABLE II.—Plasma Renin Activity (Dr. M. Crane). (mµg. Angiotensin II per 100 ml. Plasma)

		Patient	Normals	Hypertensives
Low sodium diet	Supine	9,120	150–705 (9)	176–904 (19)
	Standing	12,200	574–1240	258–3440
High sodium diet	Supine	6,000	36–236 (11)	46–1120 (19)
	Standing	6,400	237–825	
Normal diet and spironolactone	Supine	5,400		
	Standing	4,310		

¹ Values for the normals and hypertensives are ranges. The numbers of subjects are indicated in parentheses.

extremely high compared with normal subjects or patients with essential hypertension, renal hypertension, or primary aldosteronism. (Values given were ranges for each group.) Values for the patient were significantly higher on a low-sodium diet but showed no change after the period on aldactone.

¹ Measured in the laboratory of Dr. Milton Crane.

Renal Biopsy

A percutaneous renal biopsy of the right kidney was examined by light microscopy.² Haematoxylin and eosin stains revealed cellular proliferation in a few glomerular loops in a small number of the glomeruli. The juxtaglomerular cells that make up the walls of the preglomerular portion of the afferent arteriole were greatly increased in number, causing a distinct cellularity of the vascular pole of many of the glomeruli.

FIG. 3.—A glomerulus stained with haematoxylin and eosin showing increased cellularity of the vascular pole and cellular proliferation in a few capillary loops.

Periodic acid Schiff stained sections revealed P.A.S.-positive granules in the cytoplasm of the granular juxtaglomerular cells. The average number of granular juxtaglomerular cells per vascular pole was between 17 and 20, compared with four to six in normal individuals. Hence there was unquestioned hyperplasia of the granular juxtaglomerular cells. The granularity of each cell was more difficult to quantitate since human kidneys lack significant numbers of granules even in situations where the cells are known to have increased secretory activity.

Angiotensin Infusion Test

Synthetic angiotensin II amide was infused intravenously in a solution of 0.9% saline by means of an infusion pump to deliver

FIG. 4.—Effect of infusion of angiotensin II amide on blood pressure. Results in present case are superimposed on the data of Bartter *et al.* (1962). The latter are reproduced by kind permission of the *American Journal of Medicine*.

doses of 0.01, 0.05, and 0.2 $\mu\text{g./kg. body weight/minute}$. Blood pressures were recorded by sphygmomanometry during a basal period of 30 minutes and then at 60-second intervals for 8 to 10 minutes during each dose rate of angiotensin infusion. The mean systolic and diastolic blood pressures for each infusion rate were calculated and the increments in blood pressure above baseline levels

were estimated. The experiment was performed on two occasions when the serum potassium was below 3 mEq/l. Fig. 4 shows these results superimposed on data obtained from the patients studied by Bartter *et al.* (1962). It can be seen that our patient shows grossly diminished pressor sensitivity to angiotensin compared with the normal subjects and similar sensitivity to that seen in the other two patients. Expressed according to the criteria of Kaplan and Silah (1964), our patient required 70–100 $\mu\text{g.}$ of angiotensin per kg. body weight per minute to obtain a 20 mm. Hg rise in diastolic blood pressure. This compared with 2.6–7.6 mg. for normal subjects (Hocken and Kark, 1965). The normal pressor activity of the angiotensin used in our patient was confirmed in normal subjects.

The pressor response to noradrenaline was also studied by infusing noradrenaline at rates of 0.6, 1.2, and 3.0 $\mu\text{g./kg. body weight/minute}$. Average increments of 1.5, 7.2, and 24 mm. Hg in diastolic pressures were obtained for the respective doses of noradrenaline.

Discussion

The patient showed several features which suggested that he suffered from the same disease as the patients described by Pronove *et al.* (1960), Bartter *et al.* (1962), and Bryan *et al.* (1966)—namely, hypokalaemic alkalosis, evidence of hyperaldosteronism, hyperplasia of the juxtaglomerular apparatus, increased renin secretion, and presumably increased angiotensin formation, normal blood pressure, absence of oedema, and relative insensitivity to pressor effects of exogenous angiotensin.

The variably elevated urinary aldosterone levels in our patient were thought to be due to the inhibiting effect that hypokalaemia itself has on aldosterone secretion (Cannon *et al.*, 1964; Gann *et al.*, 1964). The balance studies appear to provide good evidence that the hypokalaemia was due to an aldosterone effect and values were raised after a period of potassium repletion. It is noted that preliminary values of aldosterone excretion reported by Bryan *et al.* (1966) were also normal in their patient.

Plasma renin activity was grossly raised in our patient (Table II). Despite the high levels on the sodium intake of 120 mEq/day, it appeared that the kidneys were still capable of producing more renin in response to a low sodium intake.

The increased granularity of the juxtaglomerular apparatus (Fig. 3) demonstrated by light microscopy was similar to that seen in the other patients (Bartter *et al.*, 1962; Bryan *et al.*, 1966) and provided further evidence of increased renin production.

If it is reasonable to assume that the increased renin production resulted in increased angiotensin formation and consequently hyperaldosteronism and hypokalaemia in these patients, then two outstanding questions are posed. Firstly, what is the fundamental cause of the increased activity of the juxtaglomerular apparatus? Secondly, why is the blood pressure normal in the presence of increased angiotensin and aldosterone production? It has been suggested (Bartter *et al.*, 1962; Bryan *et al.*, 1966) that the prime abnormality is a decreased vascular sensitivity to angiotensin as demonstrated by the infusion of exogenous angiotensin—the implication being that renin production is increased to produce angiotensin, which directly maintains vasomotor tone. The hyperaldosteronism would then be an unwanted side-effect of this compensatory mechanism. This theory assumes that angiotensin is of physiological importance as a peripheral vasoconstrictor. The situation is not clear in this respect, but it is apparent that any physiological pressor effect is modified and mediated at least in part by electrolyte changes and aldosterone (Peart, 1965).

Ames *et al.* (1965) showed that prolonged angiotensin infusions in normal subjects were associated with increasing pressor sensitivity coincident with increased aldosterone production and sodium retention. On the other hand, a diminished

² Kindly reported by Dr. H. Demopoulos.

pressor response to angiotensin has been described in both normotensive and hypertensive states where increased endogenous angiotensin circulates. For example, in the secondary hyperaldosteronism of cirrhotics (Ames *et al.*, 1965) and in some cases of malignant and renal hypertension (Kaplan and Silah, 1964), it has been suggested that the diminished pressor response to exogenous angiotensin in those conditions may be due to tachyphylaxis to the prolonged high levels of circulating angiotensin. Such tachyphylaxis might account for the pressor insensitivity seen in our patient. The absence of a simple alternative explanation for the increased renin production and decreased pressor response to angiotensin in these patients is presumably due to lack of knowledge of the precise mode of activation and functions of the renin-angiotensin system. It is therefore pertinent to examine two situations in which the renin-angiotensin-aldosterone system is known to be stimulated—namely, local abnormalities of renal blood flow and sodium depletion. Stemming from the experiments of Goldblatt *et al.* (1934), it has been shown that local disorders of renal blood flow may give rise to increased renin production and hypertension. A local abnormality of renal blood flow seems unlikely in our patient since hypertension was absent and the renal vasculature was grossly normal on aortography.

Sodium depletion also causes increased renin (Genest *et al.*, 1964; Brown *et al.*, 1964), angiotensin (Veyrat *et al.*, 1964), and aldosterone (Luetscher, 1956) production but without the development of either hypertension or oedema. It is therefore tempting to speculate that there is a tendency towards sodium depletion and thus extracellular fluid volume depletion in these patients. Abnormalities in extracellular fluid volume are not easy to establish, but if such a deficit were the stimulus to excess renin production then expansion of extracellular fluid or plasma volume should depress plasma renin activity, whereas if some other overriding stimulus were responsible then volume expansion would be less likely to affect renin output materially.

This theory was examined by measuring plasma renin levels before and after infusions of 0.9% saline and 6% dextran in 0.9% saline. The studies were carried out while the patient was on a constant sodium intake of 100 mEq/day. The two infusions were given four days apart and were each for four hours between 10 a.m. and 2 p.m. with the patient supine and fasted but without prior fluid restriction. Urine output and body weight were recorded every 20 to 30 minutes during the infusions. Plasma renin activity was measured immediately before and after each infusion. Plasma volume was estimated before and after the dextran infusion, using radioiodinated human serum albumin. Table III shows these results along with the volumes of fluid infused, the maximum weight increase during infusion, and the change in plasma volume after dextran. It can be seen that even when allowance was made for haemodilution plasma renin levels fell markedly with both saline and dextran infusions. The fact that at the end of the infusions renin activity, though drastically reduced, was still higher than normal may be due to the relatively short periods of volume

compared with the observed values of 918 and 654 units. If the infusions had been continued longer renin activity might well have fallen more.

It seems likely that the inhibition of renin activity with both infusions was mediated by changes in plasma volume rather than changes in extravascular volume. A total of 700 ml. of 6% dextran in saline caused plasma renin activity to fall to a similar extent to 3,700 ml. of saline, and whereas a rise in plasma volume is anticipated with both infusions, and a rise in interstitial fluid volume is expected with the saline alone, the observation that 550 of the 700 ml. of 6% dextran in saline could be accounted for by the rise in plasma volume (Table III) suggests that this infusion caused little interstitial volume expansion.

The demonstration that excess renin production could be inhibited by plasma volume expansion is compatible with the suggestion of an abnormality of fluid volume control in these patients, the increase in renin, angiotensin, and aldosterone acting in concert to retain sodium and to restore extracellular fluid volume to normal. Neither hypertension nor oedema would be expected in such a situation, and if fluid volume correction were inadequate blood pressure would tend to be low, as in these patients. A mechanism leading to subnormal extracellular or plasma volume still requires explanation. Impaired proximal tubular sodium reabsorption seems possible, as suggested by Laragh and Kelly (1964), in which case increased delivery of sodium to the distal tubule and exchange there of sodium for potassium would lead to the hypokalaemia observed.

Other features of this disorder which remain unexplained are the growth retardation and the glomerular damage. Growth retardation has been attributed to chronic hypokalaemia (Bryan *et al.*, 1966), and no better explanation is offered. Glomerular damage was widespread in the renal biopsies obtained in three of the patients. Light microscopy of the kidney in our patient showed capillary basement membrane thickening similar to that seen in many forms of glomerulonephritis. Despite this, there was no significant proteinuria. It is not clear whether these glomerular changes are related causally to the disease process or result from it. However, it has been shown that renin injections cause glomerular damage and proteinuria (Pickering and Prinzmetal, 1940), and it is possible that prolonged excessive release of endogenous renin might have a similar though less marked effect.

Management of our patient has been on the basis of spironolactone therapy to increase the serum potassium with attempts to administer up to 400 mg. a day, and though the drug is taken irregularly the serum potassium remains at 3.2–3.5 mEq/l., which is higher than the levels originally observed (Bartter *et al.*, 1962). The blood pressure has not changed significantly despite the initial saluresis caused by spironolactone. The patient appears to be more alert and active but he is receiving testosterone injections, which may influence this impression. No surgery is contemplated, since two of the three other patients had subtotal bilateral adrenalectomy with no immediate or long-term effect on their hypokalaemia and no symptomatic improvement.

Summary

A disorder characterized by hypokalaemia, evidence of hyperaldosteronism, increased plasma renin activity, increased granularity of the juxtaglomerular apparatus, glomerular abnormalities, normal blood pressure, and decreased pressor response to exogenous angiotensin is described in a non-oedematous 18-year-old prepubertal negro youth and is compared with a similar condition described in three other patients (Pronove *et al.*, 1960; Bartter *et al.*, 1962; Bryan *et al.*, 1966).

TABLE III.—Effect of Fluid Volume Expansion of Plasma Renin Activity

Infusion:	0.9% Saline	6% Dextran in 0.9% Saline
Plasma renin activity { Before ..	10,700 units	4,870 units
{ After ..	918	654
Volume infused ..	3,400 ml.	700 ml.
Maximum weight increase during infusion ..	1.2 kg.	0.5 kg.
Plasma volume { Before ..		1.81 l.
{ After ..		2.36 "

expansion compared with the biological half-life of renin. Data on the latter are scanty. In the dog it has been estimated as 15 minutes (Fasciolo *et al.*, 1964) and is probably longer in man. With a half-life for renin of say 30 minutes and volume expansion for three of the four hours of infusion, initial values of 10,700 and 4,870 units should fall to 446 and 203 units,

The pathogenesis of the syndrome is discussed and evidence for an abnormality of extracellular fluid volume control is presented.

We wish to acknowledge the invaluable assistance of the Metabolic Unit Staff at the Los Angeles County General Hospital in studies of this patient.

Total Parathyroidectomy in Treatment of Secondary (Renal) Hyperparathyroidism

C. S. OGG,* M.B., B.SC., M.R.C.P.

Brit. med. J., 1967, **4**, 331-334

Recent improvements in the care of patients with chronic renal failure have revealed that symptoms attributable to renal glomerular (uraemic) osteodystrophy develop in a considerable number of cases.

The various components of this bone disease include rickets or osteomalacia, osteitis fibrosa, and osteosclerosis. These may occur in almost pure forms but more commonly appear in varying combinations in different patients.

Treatment with large doses of vitamin D (Liu and Chu, 1943; Dent *et al.*, 1961; Stanbury and Lumb, 1962) is often successful in promoting healing of the skeleton, but is dangerous because of the ease with which it is possible to produce hypercalcaemia and metastatic calcification. This danger is greatest in those patients who have osteitis fibrosa as the dominant skeletal lesion, and who, unlike the majority of patients with renal failure who have low plasma calcium levels (de Wesselow, 1923), have plasma calcium levels that are either within the normal range (Stanbury and Lumb, 1966) or even frankly raised (Hubbard and Wentworth, 1921; Smyth and Goldman, 1934; Shelling and Remsen, 1935).

Stanbury *et al.* (1960) were the first to embark deliberately on a policy of subtotal parathyroidectomy in a patient with severe secondary hyperparathyroidism, and they were subsequently able to heal the bone lesions with vitamin D without producing hypercalcaemia. Since then further reports have appeared in this country (Findley *et al.*, 1961), in South Africa (Stables *et al.*, 1964), and in the United States of America (Anderson *et al.*, 1963; Fordham and Williams, 1963; Golden *et al.*, 1965; Felts *et al.*, 1965; Wilson *et al.*, 1965). These reports include a total of only 12 cases, and it is considered worth while to report four more.

Case 1

A 43-year-old man presented in 1961 with severe chronic renal failure (plasma urea 210 mg./100 ml.). No cause for this was found, and he was treated with a high fluid intake, a low protein diet, and sodium bicarbonate 2 g. daily.

During the following year he developed radiological changes of hyperparathyroidism in his hands, but this caused no symptoms until 1964, when he felt severe pain in both shoulders. His plasma calcium had risen to 10.5 mg./100 ml. (Fig. 1), with an ionized fraction of 5.0 mg./100 ml. and a complexed fraction of 1.3 mg./100 ml. (normal range 4.9-5.8 and 0.0-0.7 mg./100 ml. respectively (L. Watson, personal communication, 1967). X-ray films showed progression of the subperiosteal erosions of the phalanges and the appearance of erosions of the lateral ends of both clavicles.

FIG. 1.—Case 1. Biochemical progress. Note changing time scale.

It was also noted that there was a considerable amount of calcification in the internal iliac arteries. Because of the metastatic calcification total parathyroidectomy was recommended, and four hyperplastic glands were removed. Preoperative and postoperative findings are shown in Tables I and II.

The plasma calcium fell to a minimum of 4.9 mg./100 ml. on the fifth postoperative day, and symptoms of tetany were controlled with intravenous calcium gluconate and oral dihydrotachysterol. Within a month he had lost his bone pain and was discharged.

* Medical Registrar, St. Peter's, St. Paul's, and St. Philip's Hospitals, London W.C.2. Present address: Renal Unit, Guy's Hospital, London S.E.1.

from hospital taking oral dihydrotachysterol and calcium supplements. The doses of these were reduced until they were stopped in September 1965.

His renal disease continued to progress, but at the time of writing he was still working full time.

Case 2

In 1961 an 11-year-old boy had a urinary tract infection. Investigation revealed moderate renal failure (blood urea 91 mg./100 ml.) and bladder-neck obstruction with ureteric dilatation. Despite relief of the obstruction his blood urea remained raised, and he continued to have episodes of infection.

Two years later he first had pains in his legs, and in 1964 he was referred for further investigation. The presence of severe renal failure (blood urea 237 mg./100 ml.), together with a urinary infection, was confirmed. Plasma calcium was 10.3 mg./100 ml.,

and there was gross elevation of the plasma alkaline phosphatase (84 K.A. units/100 ml.) (Fig. 2). A radiological skeletal survey showed epiphyseal changes suggestive of rickets, together with subperiosteal erosions on the phalanges, resorption of the phalangeal tufts (Figs. 3 and 6), erosion of the lateral ends of the clavicles, and a "rugger jersey" spine. Dietary protein restriction, antibiotics, and a high fluid intake led to a fall in blood urea but did not affect his skeletal symptoms. The addition of calciferol resulted in clinical and radiological improvement, but was associated with hypercalcaemia (11.6 mg./100 ml.), which persisted despite

reduction of dosage and eventual cessation of treatment in November 1965. By this stage his symptoms had returned, and when reassessed in January 1966 he was incapacitated by pain in his legs and had developed a waddling gait. His renal function had deteriorated, and x-ray films showed that the changes of secondary hyperparathyroidism had become more pronounced, while the changes suggesting rickets had if anything regressed (Figs. 4 and 6). Plasma calcium fractionation showed an ionized fraction of 5.7 mg./100 ml. (Table I) and a complexed fraction of 1.4 mg./100 ml. Total parathyroidectomy was advised, and four hyperplastic glands were removed.

FIG. 6.—Case 2. X-ray films of right middle finger. Left, 2 October 1964. Centre, 6 January 1966. Right, 30 March 1966.

Postoperatively he developed severe hyperkalaemia (8.7 mEq/l.) but responded to conservative treatment for this. Within 24 hours the plasma calcium fell to 6.2 mg./100 ml.; subsequently it was maintained at this level, with intravenous calcium gluconate, intramuscular parathyroid hormone, and oral dihydrotachysterol (Table II). Four days later treatment was reduced to oral dihydrotachysterol with a calcium supplement. His bone pain disappeared within three weeks, and two weeks later there was obvious radiological improvement (Figs. 5 and 6). The dose of dihydrotachysterol was reduced, being finally stopped in April.

Unfortunately his renal function continued to deteriorate, but he remained free of bone pain until his death in July 1966. Necropsy was not performed.

Case 3

A 42-year-old woman had had acute nephritis at the age of 13, and in 1953 she was seen with proteinuria and a raised blood urea (70 mg./100 ml.). Ten years later she was referred because of progressive deterioration in renal function (blood urea 125 mg./100 ml.). Routine skeletal survey revealed changes of hyperparathyroidism with erosion of the borders of the phalanges and of the phalangeal tufts. Her plasma calcium was 11.1 mg./100 ml. (ionized fraction 6.0 mg./100 ml., complexed fraction 1.3 mg./100 ml.) with a plasma alkaline phosphatase of 40 K.A. units/100 ml. (Table I). At parathyroid exploration only two glands could be identified (Table II). Both were enlarged, but one (2.51 g.) was much larger than the other (0.17 g.). Despite this the histological appearances were thought to favour a diagnosis of secondary hyperplasia rather than of adenoma. Within 24 hours the plasma calcium and phosphate fell to 7.0 and 3.9 mg./100 ml. respectively. Calciferol 1.25 mg. on alternate days was started, and two weeks later she was discharged from hospital.

Subsequently, though there was radiological evidence of improvement of the bone lesions, her renal function continued to deteriorate

until her death nine months later. Necropsy revealed granular contracted kidneys compatible with the diagnosis of chronic glomerulonephritis.

Case 4

A 14-year-old girl presented in February 1962 with chronic renal failure (plasma urea 170 mg./100 ml.). Investigations revealed a solitary contracted right kidney and radiological evidence of hyperparathyroidism with erosion of the borders of the phalanges. She was treated with a high fluid intake, moderate protein restriction, and sodium bicarbonate 3 g. daily.

Fifteen months later she first complained of pain in the shoulders and legs. Further x-ray films revealed progression of the bone disease with severe changes in the hands, clavicles, and skull. There was extensive arterial calcification with metastatic deposits of calcium adjacent to several interphalangeal joints. Her renal function had deteriorated further, and the plasma calcium had risen to 10.2 mg./100 ml. (ionized fraction 5.6 mg./100 ml., complexed fraction 0.8 mg./100 ml.), with a plasma alkaline phosphatase of 42 K.A. units/100 ml. (Table I). Parathyroidectomy was advised, and four hyperplastic glands were removed (Table II). Postoperatively, continued haemorrhage necessitated re-exploration and drainage of the wound. Her plasma calcium and phosphate fell to 5.6 and 6.3 mg./100 ml. respectively on the third day. That evening she died unexpectedly, and subsequently her plasma potassium was found to have risen to 7.9 mEq/l.

Discussion

It is apparent that parathyroidectomy and subsequent treatment with large doses of vitamin D may allow healing of the bone lesions of secondary (renal) hyperparathyroidism without inducing hypercalcaemia. Once the bone lesions have healed the amount of vitamin D required to keep the patients free of symptoms attributable to hypocalcaemia may diminish, and in two of the cases it was possible to withdraw vitamin D altogether.

The operations did not influence the progress of the primary renal disease. In Cases 2 and 3 they were clearly performed too late to be of any great value to the patients. Case 1, however, experienced considerable benefit, and in retrospect it would seem that earlier operation in Case 2 might have saved the patient months of invalidism.

The progress (Figs. 3, 4, and 6) of the bone disease in Case 2 during the initial phase of treatment with vitamin D seems to contradict the view that hyperparathyroidism develops secondarily to the calcification defect of renal glomerular osteodystrophy. In these circumstances one might have expected the osteitis fibrosa to heal when the rickets was treated. However, the hyperparathyroidism which is commonly associated with osteomalacia of dietary origin, and which usually remits when the latter is treated, may occasionally become autonomous (Davies *et al.*, 1956). There is evidence that this may happen in patients with secondary (renal) hyperparathyroidism, for at least six patients have been subjected to parathyroidectomy only after successful renal transplantation had revealed the classical biochemical findings usually associated with primary hyperparathyroidism (McPhaul *et al.*, 1964; Wilson *et al.*, 1965; McIntosh *et al.*, 1966). In each case four enlarged glands were found.

Most patients with renal failure have low plasma ionized calcium levels (Fanconi and Rose, 1958; Walser, 1962), and the finding of a raised (Case 3) or high normal (Cases 2 and 4) level suggests that parathyroid autonomy has developed and is a strong indication for parathyroidectomy. Less definite indications include the presence of metastatic calcification and the failure of treatment with vitamin D to heal the skeleton without inducing hypercalcaemia.

In order to avoid the possibility of recurrence of the hyperparathyroidism, total rather than subtotal parathyroidectomy was advised. In consequence the fall observed in the plasma

calcium level was profound. This might be expected to sensitize the myocardium (Meroney and Herndon, 1954) to the rise in plasma potassium that may occur in any patient with renal failure who has had a major operation. This combination of events was presumably responsible for the death of Case 4. The postoperative fall in plasma phosphate is the opposite to what is seen in patients who have had a parathyroidectomy for primary hyperparathyroidism. This was found also by Stanbury *et al.* (1960), who pointed out that, as the normal phosphaturic effect of exogenous parathyroid hormone does not occur in the presence of a reduction in creatinine clearance to less than 10 ml./minute (Goldman and Bassett, 1954), parathyroidectomy would not be expected to change the renal phosphate clearance. Though the urinary excretion of phosphate fell postoperatively in all the patients, the fall was no greater than would be expected from that in the plasma level, and presumably the fall in the plasma level is due to the deposition of phosphate with calcium in bone.

The practical problems imposed by the appearance of autonomous hyperparathyroidism after successful renal transplantation are considerable. At least one transplanted kidney has been affected by calculi associated with autonomous (secondary) hyperparathyroidism (Hume *et al.*, 1966), and in any case the dangers of parathyroidectomy must be increased considerably by the immunosuppressive and steroid therapy that these patients receive. Thus if the presence of hyperparathyroidism is recognized it is probably advisable to deal with it before embarking upon transplantation.

Summary

Previous experience of the use of parathyroidectomy in the treatment of secondary (renal) hyperparathyroidism has been reviewed briefly. Four further cases are reported, and it is suggested that, with increasing interest in the management of chronic renal failure, the operation may be performed more

often in the future than it has been in the past. The indications for and the timing of surgery are discussed.

I wish to thank Dr. A. M. Joeckes and Dr. A. R. Harrison for permission to report these cases. Mr. J. D. Fergusson performed all the operations and Dr. L. Watson carried out the plasma calcium fractionations.

Syndrome of Sclerodactyly, Calcinosis, Raynaud's Phenomenon, and Telangiectasia

A. W. DELLIPIANI,* M.B., M.R.C.P.ED.; M. GEORGE,† M.B., B.S.C., M.R.C.P., M.R.C.P.ED.

Brit. med. J., 1967, **4**, 334–335

Since Thibierge and Weissenbach (1911) described the association between scleroderma and calcinosis the Thibierge-Weissenbach syndrome has come to mean anything from progressive systemic sclerosis with calcinosis (Durham, 1928) to a much more benign syndrome in which sclerodactyly, calcinosis, and Raynaud's phenomenon are associated with telangiectasia (Prosser Thomas, 1942). In the 10 years preceding 1964 only 18 cases with this clearly defined syndrome had been reported, and to these Winterbauer (1964) added another seven. The present report describes three further cases and reviews the prognosis in this syndrome.

Case 1

A 66-year-old woman gave a history of Raynaud's phenomenon in the hands since the age of 20, which had been more of an inconvenience than a disability. The most recent admission was caused by an exacerbation of dyspnoea, which had been present for

two to three years. There was no family history of telangiectasia or of recurrent haemorrhagic episodes to suggest this.

Some rheumatoid deformity was present in the hands, there was also sclerodactyly and a thickened subcutaneous plaque in the left forearm. Telangiectatic spots were present on the lips, the buccal mucosa, and the hands. Other abnormal findings were a raised jugular venous pressure and a cardiac apex in the sixth space outside the midclavicular line, the impulse being left ventricular in type. A mitral grade III regurgitant systolic murmur was audible at the apex with a third heart sound. Marked dorsal kyphosis was present, and the liver was enlarged one fingerbreadth and was soft.

The abnormal findings on investigation were that the chest x-ray film showed left ventricular enlargement with pulmonary congestion. Radiographs of the hands showed contractures of the thumbs and fifth fingers of both hands with soft-tissue calcification in the fingers (see Fig.). Respiratory function tests demonstrated impaired vital capacity (1,350 ml.; predicted 1,900 ml.) with increased residual volume (2,460 ml.; predicted 1,800 ml.). There was evidence of obstructive airway disease, the ratio F.E.V.₁/F.V.C. being 56%. O₂ saturation was 86%; Pco₂ 38 mm. Hg; pH 7.40. The findings were thought to be compatible with the presence of pulmonary congestion and kyphoscoliosis.

* Department of Therapeutics, the Royal Infirmary, Edinburgh 3.
 † Department of Cardiology, the Royal Infirmary, Edinburgh 3.

Case 2

A 51-year-old woman gave a 30-year history of Raynaud's phenomenon. At times she had developed white lumps in the fingers, which were incised and took months to heal. In 1942 she had a right-sided cervical sympathectomy and 20 years later a right-sided lumbar sympathectomy for ischaemic symptoms in the feet. In addition, she had had the right index and middle fingers amputated, and in 1959 a local excision of a palatal angiomatous lesion because of recurrent bleeding. The most recent admission was caused by an exacerbation of ischaemic symptoms in the hands. There was no history of telangiectasia or of recurrent epistaxes, haemoptyses, or haematemesis in the family.

She was a thin woman, and had sclerodactyly with marked soft-tissue calcification. Telangiectatic spots were noted on the lips and the buccal mucosa. The blood pressure was 180/100 mm. Hg.

Radiograph of hands in Case 1.

The abnormal findings on investigation were that x-ray films of the hands showed marked calcification of the soft tissues. X-ray film of the chest showed slight cardiomegaly and the changes of chronic bronchitis and emphysema, while barium swallow showed slight oesophageal atony and dilatation.

Two of the patient's siblings examined by us were normal.

Case 3

A 35-year-old woman gave a 15-year history of Raynaud's phenomenon in both hands. In the previous three months this had become worse, and she had developed ulcers on the third digits of both hands. She had had varicose veins since the birth of the first of her three children nine years previously, and the immediate cause for admission was the development of a superficial thrombosis of the long saphenous vein in the left leg. There was no previous history of jaundice and no history to suggest telangiectasia in the family, which included four brothers and one sister.

Sclerodactyly was present with ulceration of the skin of both third digits. Telangiectatic spots were present on the lips and the surrounding skin, on the buccal mucosa, and on the hands.

The abnormal results of investigation were as follows: Serum alkaline phosphatase 76 and 63 K.A. units; S.G.P.T. 44 S.F. units; S.G.O.T. 54 S.F. units; 5-nucleotidase 181 and 141 i.u./l. The total serum proteins were 6.4 g./100 ml. (albumin 3.7 g.), and the electrophoretic pattern: α_1 -globulin 0.2 g./100 ml.; α_2 -globulin 0.9 g./100 ml.; β -globulin 0.9 g./100 ml.; and γ -globulin 0.7 g./100 ml. X-ray films of the hands showed decalcification and erosion of the heads of the middle phalanges on both sides and of the proximal phalanx of each middle finger. Calcification was present in the soft tissues of the middle fingers and the right index finger, mainly related to the interphalangeal joints.

None of the siblings lived in the area, and were therefore not examined. The patient's three children, aged 6 to 9 years, were examined and no telangiectatic lesions were noted.

Discussion

There is nothing to distinguish the telangiectasia in this condition, either in appearance or distribution, from the lesions in patients with hereditary telangiectasia. It has been suggested, however, that the lesions appear later than in the hereditary condition, where they usually occur in the second to the fourth decade—though they may be present in childhood (de Gruchy, 1964). It is also said that there is less tendency to haemorrhagic episodes, and that the telangiectatic lesions are not hereditary in this syndrome, where there is also a predominance of affected females (Winterbauer, 1964). None of our three patients gave any family history suggesting telangiectasia. Only Cases 1 and 3 could recall roughly when their lesions appeared, the former when well into her fifties and the latter just after the age of 20. Only Case 2 had been troubled by bleeding, which originated from a palatal lesion.

The occurrence of signs of systemic scleroderma in the syndrome of sclerodactyly, calcinosis, Raynaud's phenomenon, and telangiectasia is well recorded. Case 2 had oesophageal involvement, while Case 3 had abnormal liver-function tests. Though the latter was initially treated with phenindione, the abnormal findings persisted a year after stopping this drug. Sclerodermatous hepatic involvement is said to be extremely rare (Tuffanelli and Winkelmann, 1961). Calvert *et al.* (1958) described two cases of severe portal hypertension associated with hepatic fibrosis in two patients with systemic fibrosis, and Batsakis and Johnson (1960) reported systemic scleroderma in a patient with a pulmonary adenocarcinoma who had hepatic fibrosis. We feel that the abnormalities in our patient are most likely to be due to sclerodermatous involvement of the liver. Because of the possibility of visceral telangiectasia hepatic biopsy was not attempted.

It has been emphasized that the progress of the disease in patients with this syndrome is slow even in the presence of systemic involvement (Winterbauer, 1964). Though rare, the syndrome appears to come under the general heading of "acrosclerosis" (Sellei, 1934). In contrast, diffuse scleroderma (progressive systemic sclerosis) is a rare condition (Tuffanelli and Winkelmann, 1961) with a poor prognosis, the five-year survival being of the order of 50% (Farmer *et al.*, 1960).

Summary

Three cases of sclerodactyly, Raynaud's phenomenon, calcinosis, and telangiectasia are described. The syndrome appears to be a rare variant of the most common form of presentation of scleroderma "acrosclerosis." The occurrence of systemic manifestations is noted, but the fact that this type of scleroderma tends to run a relatively benign course is emphasized.

We would like to express our thanks to Dr. C. Burt, Mr. R. J. M. McCormack, and Professor R. H. Girdwood for permission to describe these cases.

Medical Memoranda

Incest, Inbreeding, and Mental Abilities

Brit. med. J., 1967, 4, 336-337

Two recent communications have intimated the extent of the disadvantages from which children of incestuous unions may suffer. Adams and Neel (1967) reported that of 18 offspring from unions between first-degree relatives only seven were normal, one died at 6 hours and one at 15 hours, one died at 2 months from glycogen storage disease, one had a bilateral cleft lip, and two were severely mentally retarded with seizure disorder and spastic cerebral palsy, and five mildly so (I.Q.s 50 to 70 on repeated testing); thus seven were of subnormal mental standard. Carter (1967) reported the conditions seen in 13 children of similar unions; only five were normal, three failed to reach the age of 9 years (dying at 13 months from cystic fibrosis, at 21 months from progressive cerebral degeneration with blindness, and at 8 years from a congenital heart defect respectively), and one is severely mentally retarded and four mildly so (I.Q.s 50 to 76); thus five are of subnormal mental standard, making a total in the two series of 12 out of 31.

Since incest as defined in Western society is merely the extreme and socially designated form of consanguineous union, mating between related individuals, evidence of association between less close degrees of parental consanguinity and mental abilities of offspring is of relevance to the interpretation of these findings. The results of a preliminary analysis of consanguinity and mental ability in a small closed population are presented here.

CONSANGUINITY

The most extreme form of consanguineous union that can occur in man, and which gives rise to the most highly inbred offspring, is mating between two first-degree relatives (father/daughter, brother/sister, son/mother). A child is said to be inbred if he is born of a mating between two individuals who can both trace descent from a common ancestor, so that both the genes that the child possesses at a given locus may be replicates of a single gene that was present in the common ancestor and so may be identical.

The probability that both the genes an individual possesses at a given autosomal locus are identical is measured in terms of Wright's inbreeding coefficient (F), which therefore also indicates the proportion of autosomal loci at which the individual is expected to be an identical homozygote. By this measure inbreeding can be quantified. Offspring of incestuous unions between brother and sister or between father and daughter have an inbreeding coefficient of 0.25; offspring of a marriage between two first cousins have an inbreeding coefficient of 0.0625; both of these figures will be increased if any common ancestor was himself inbred. Mating of two completely unrelated individuals produces offspring with an inbreeding coefficient of zero. It is this likelihood of increased homozygosity in inbred individuals that is responsible for the increased frequency of manifestation expected in them of simple recessive characters, and for the increased frequency of those extreme conditions which represent the tails of the distribution curves of continuously varying quantitative attributes brought about by polygenic action.

ANALYSIS OF RECORDS FROM TRISTAN DA CUNHA

From the extensive records that are available for the population of Tristan da Cunha, based largely on those collected by

Dr. L. Woolley when resident on the island in 1942, supplemented by those obtained by Dr. P. Munch during an expedition to the island in 1938 and more recently by Dr. J. Loudon, it is possible to trace the descent of every individual from the founders of the population, and so calculate his inbreeding coefficient. This has been done for every present and past member of the Tristan population (Roberts, 1967). Dr. Woolley at the same period also recorded conditions of clinical interest, among which was his assessment of the mental capabilities of each member of the then population. These he classified, by clinical appraisal over long periods, into six broad categories from normal to low-grade mental defective. The association of these assessments with the inbreeding coefficients has been examined.

Table I sets out the mean inbreeding coefficient found in each intelligence category. There seems to be a tendency for the mean inbreeding coefficient to be higher in the lower intelligence categories (column 2). That this is almost but not entirely due to there being a greater proportion of non-inbred individuals in the higher categories (column 5) is shown by comparison with the mean inbreeding coefficient calculated for the inbred alone in each category (column 6). From Table II, setting out

TABLE I.—Inbreeding and Intelligence

Intelligence Category	Mean F	Total No. of Individuals	Individuals Not Inbred		Mean F in those Inbred
			No.	%	
1. Normal ..	0.0188	35	17	48.6	0.0366
2. Slow cerebration ..	0.0391	53	11	20.8	0.0505
3. Very slow cerebration ..	0.0379	60	16	26.7	0.0517
4. Definitely inferior mental capacity ..	0.0480	45	6	13.3	0.0554
5. High-grade mental defective ..	0.0457	8	1	12.5	0.0522
6. Low-grade mental defective ..	(0.0313)	1	0	0	(0.0313)

TABLE II.—Number of Individuals by Mental Category and Inbreeding Coefficient

F	Intelligence Category						Total No. of Individuals
	1	2	3	4	5	6	
0	17	11	16	6	1	—	51
<0.03	9	18	13	12	2	—	54
<0.06	5	10	12	5	2	1	35
<0.10	3	11	16	19	2	—	51
>0.10	1	3	3	3	1	—	11

the number of individuals by intelligence category and inbreeding coefficient, the association can be seen to be highly significant at the 1% level ($\chi^2=22.85$, 9 degrees of freedom).

COMMENT

Full allowance has to be made for the subjective nature of the classification of mental ability in interpreting these preliminary findings, which are being followed up by Dr. Keir, using the results of objective tests of intelligence. This association could mean that some of the worse mental conditions in this population are due to inbreeding so far; but the alternative explanation is also reasonable—that those of poor mental capacity tend to breed more closely if opportunity offers. Of these two explanations the second is supported in Adams and Neel's (1967) series by some of their father/daughter, but not by their 12 brother/sister, incestuous unions. In all except one of the latter the matings were between sibs of normal intelligence (I.Q.s 90 to 120, with mean values 110 in males and 103 in females), and the occurrence of mental retardation in four of

their offspring suggests an inbreeding effect. There is further supporting evidence from Japan, where Schull and Neel (1965) examined seven various indicators of school attainment—for example, performance in language or science—in relation to inbreeding, taking into account age, school grade, and socio-economic status. They observed a consistent and significant depression in performance in all seven indicators with inbreeding; by comparison with the outbred mean there was a reduction of 1% in performance per increase of 1% in F. It seems that, like physical dimensions, performance in neuromuscular tests, and other quantitative characters, mental capabilities may well be particularly susceptible to the effects of inbreeding.

The view was long since expressed that intelligence is under polygenic control, and there is much evidence to support it. On the other hand, Morton's (1960) analysis of Penrose's data suggested to him the influence of major autosomal recessive genes in an appreciable proportion of cases of severe mental defect. The present findings, which relate to less severe conditions, also suggest that some of the genes tending to lower

mental capabilities are recessive. It seems more reasonable, however, to interpret the results as indicating not control by major recessive genes but polygenic control with directional dominance, a suggestion which carries wide implications. But since the highest category here employed was "normal" and exceptionally able individuals were not distinguished, the data do not establish it. For this purpose information on the relative numbers of offspring of consanguineous unions who are above as well as below average in ability is required.

Tongue Pain with Giant Cell Arteritis

Brit. med. J., 1967, 4, 337

Local effort pain of the tongue is described as a feature of giant cell arteritis in this case report.

CASE REPORT

A previously fit 78-year-old man woke with severe neck pain which radiated over his head and was attributed to cervical spondylosis. Two weeks later he began to experience increasing malaise and pain in the tongue. This was felt diffusely at the back of his tongue and was described as a tired ache; on one occasion it followed a prolonged period of talking, but otherwise occurred only on eating, and had prevented him from taking solid food for four weeks when he was referred to hospital on 8 March 1967. It was found that eating solid food was limited after two minutes by onset of the pain, which then after a further half-minute gradually faded over the next five minutes. The pain could also be reproduced by rapid repeated protrusion of the tongue, but not by drinking or by repeated jaw movements alone.

The tongue and the temporal and occipital arteries appeared clinically normal and there were no bruits over the carotid arteries. Neck movements were limited by cervical spondylosis. There were no other abnormal findings on physical examination.

Biopsy of the right temporal artery was performed. The histological features were those of giant cell arteritis, with thrombosis, and recanalization of the lumen. Haemoglobin was 14.8 g./100 ml., white blood cell count 13,000/cu. mm. with a normal differential count, and erythrocyte sedimentation rate 34 mm. in one hour (Wintrobe).

Corticosteroid therapy was started. One week later the malaise and tongue pain had resolved.

COMMENT

Giant cell arteritis is a widespread vascular disorder (Meadows, 1966). Pain in the jaw muscles on chewing has been regarded as a typical feature of the disease (Robertson, 1952; Meadows, 1954; Ross Russell, 1959), and Meadows (1966) has noted that pain may radiate to the tongue.

Missen (1961) found histological evidence of lingual arteritis in all of five patients whose tongues had appeared normal. However,

clinical evidence of tongue ischaemia is uncommon. Gangrene of the anterior part of the tongue has been reported in five cases (Howard and Cremin, 1959; Wise, 1959; Brearley and Macdonald, 1961; Pitt *et al.*, 1961; McGill, 1961; Davis and Davis, 1966). Swelling of the tongue (Wolinetz *et al.*, 1948; Cornil *et al.*, 1949), a sensation that the tongue was too big (Meadows, 1954), and constant pain or burning of the tongue (Bowers, 1940; Post, 1949; Olivo and Spizzo, 1951) have also been noted, but local effort pain of the tongue does not appear to have been previously described.

Early recognition and treatment of giant cell arteritis is a matter of urgency. The present case has therefore been reported to show that angina of the tongue may be a presenting symptom of the disease, histological confirmation of which can be obtained from biopsy of a clinically normal temporal artery (Alestig and Barr, 1963).

My thanks are due to Dr. K. D. Lawrey for referring this patient and to Dr. G. Stewart Smith for the histological report.

A. H. HENDERSON, M.B., M.R.C.P.

Royal Devon and Exeter Hospital,
Exeter.

Bacterial Endocarditis Presenting as Pseudobulbar Palsy

Brit. med. J., 1967, 4, 338

The changing pattern of bacterial endocarditis has been attributed to the declining incidence and severity of rheumatic fever; the increasing involvement of elderly individuals, often without cardiac murmurs; the increase of opportunistic infection; and infection with organisms formerly rarely associated (Uwaydah and Weinberg, 1965). Diagnostic delays have been prominent in the failure to reduce the mortality rate in recent years. Petechiae offer a valuable clue, being present in about half the cases, but can be readily overlooked, since few may be visible at a time. The diagnostic complexities are illustrated by the present case.

CASE REPORT

The patient, a man aged 61, had developed weakness, breathlessness, anorexia, and loss of weight in the past few months. His gait was affected and he was able to walk only progressively shorter distances, until finally he was virtually bed-ridden; simultaneously his speech became indistinct and his swallowing ability so impaired that he had attacks of choking during meals. Incontinence of urine had existed for several weeks. He had become dull and apathetic. His wife had died six months previously. Since then he had been depressed, his condition being attributed to an emotional reaction.

On examination he was extremely ill, wasted, and dehydrated, and responded very little or not at all to repeated questioning. Dysarthria was obvious when he did speak, as was dysphagia when tested with the drinking of water. A petechial haemorrhage was observed on eversion of the left lower lid but not in the optic fundi. The heart was not enlarged; an apical mid-systolic murmur was audible. The pulse was regular and rapid and the temperature was 99.2° F. (37.3° C.). No finger-clubbing, splinter haemorrhages, sternal tenderness, or splenomegaly were observed. The other abnormal physical findings were confined to the C.N.S.—exaggeration of all the deep reflexes and bilateral plantar extensor responses.

The significant results of the special investigations were: chest and skull x-ray films: no abnormalities; Hb 9.6 g./100 ml.; M.C.H.C. 28.5%; W.B.C. 12,000/cu. mm. (92% polymorphs); blood urea 38 mg./100 ml.; urine microscopy: only an occasional leucocyte; faecal occult blood examination (3) negative; total serum protein 5.5 g./100 ml. (albumin 2.8 g., globulin 2.7 g.), electrophoresis showed only moderate increase of gammaglobulin; C.S.F. examination—20 cells/cu. mm. (60% lymphocytes, 40% polymorphs), protein 70 mg./100 ml., an increase of globulin, sugar 60 mg./100 ml., and no growth on culture. Wassermann reaction of blood and of C.S.F. was negative.

A blood culture yielded a growth of *Streptococcus viridans* sensitive to penicillin and streptomycin. Treatment with both was instituted and the clinical response was soon apparent. With the improvement of his general condition a progressive reduction occurred in the neurological abnormalities, so that his gait, speech, and swallowing returned to normal and the objective neurological features and his mental apathy disappeared. A progressive rise in his haemoglobin and fall in the W.B.C. followed. The C.S.F. examined a month after the original lumbar puncture showed 5 cells/cu. mm., protein 55 mg./100 ml., and only slight increase of globulin.

DISCUSSION

Cerebral disturbances are prominent in many patients with bacterial endocarditis. Among the presentations are meningitis (sterile or purulent, especially with pneumococcal and staphylococcal infections), convulsions, subarachnoid haemorrhage, cerebral abscess, hemiplegia and other forms of paralysis of an upper motor neurone type, and rarely a flaccid palsy. Embolization, late in the course of bacterial endocarditis is not rare, even up to two years after bacteriological and clinical cure. It is now also appreciated that in the course of the infection

local inflammatory changes arise in the wall of the capillaries and arterioles, possibly as an immunological response to the infection (Friedberg, 1966). Dominating the picture may be the features of a toxic organic psychosis (Antel, Rome, Geraci, and Sayre, 1955). An analysis of 116 cases of bacterial endocarditis revealed that neurological manifestations were present in 37, and 33 of these offered an immediate diagnostic problem—15 with strokes and seven with meningitis or meningo-encephalitis (Harrison and Hampton, 1967). Thompson (1964) stressed that bacterial endocarditis may masquerade as a simple cerebrovascular lesion, particularly if no symptoms antedate the sudden onset of, for example, a hemiplegia.

Difficulties may also exist in differentiation from the cerebral effects of rheumatic heart disease complicated by embolism, and the rheumatic fever process itself can induce abnormalities of the cerebral vasculature. Both embolization and markedly diminished blood flow can lead to neurological disorders in established valvular disease (Daley, Mattingly, Holt, Bland, and White, 1951). Hutchinson and Stock (1963) observed an incidence of clear-cut recurrent neurological symptoms of short duration equal to that of cerebral embolization in patients with rheumatic heart disease, their frequency correlating with the severity of the cardiac lesion and often being precipitated by exertion. The neurological symptoms included visual features (the most frequent), vertigo, motor and sensory symptoms, and drop seizures. Cerebral emboli in patients with mitral stenosis may cause epileptic seizures; in 20 out of 22 such cases the convulsive attacks were ascribed to previous cerebral emboli (Baker and Finnegan, 1957). A useful guide is offered by Friedberg (1966): while systemic arterial embolization in mitral valve disease may occur occasionally in sinus rhythm, bacterial endocarditis should be investigated as a more probable cause.

Recognition that non-bacterial thrombotic endocarditis has clinical as well as pathological significance is relatively recent. It may simulate a bacterial infection; embolization may provide the predominant clinical manifestations, and in such circumstances, especially in a patient with cardiac decompensation, bacterial endocarditis and mural thrombi of the cardiac chambers have to be differentiated. In the third group no embolization has taken place and the valvular lesions constituted an incidental finding at necropsy. The most commonly associated diseases in the series of MacDonald and Robbins (1957) were carcinoma (36%), heart failure (30%), and vascular thrombosis (27%). Healed bacterial and healed rheumatic endocarditis require differentiation from non-bacterial thrombotic endocarditis, as does the atypical verrucous endocarditis of Libman-Sacks in patients with disseminated lupus erythematosus.

Though much less common today, a syphilitic infection must always be excluded when neurological and cardiological features coexist. Finally, the murmurs, fever, anaemia, abnormality of serum proteins, and raised blood sedimentation rate of myxoma of the auricle simulate bacterial endocarditis; petechiae and embolic phenomena add further to the possibilities of confusion (Goodwin *et al.*, 1962).

Current Practice

DISEASE OF THE DIGESTIVE SYSTEM

Duodenal Ulcer—II

IAIN E. GILLESPIE,* M.D., F.R.C.S.

(Last week Mr. Gillespie considered the diagnosis and medical management of duodenal ulcer. This week's article deals with the indications for operation and the type of operation that can be done. It ends with a list of references to both articles.)

Indications for Elective Operation

The commonest reason for advising operation in a patient with duodenal ulcer is the failure of simple conservative medical measures to control the symptoms adequately. Few patients are considered for surgical treatment before the clinician is satisfied that the measures outlined above have been conscientiously applied, and that in spite of these measures relapses of typical ulcer dyspepsia have become more frequent, more severe, and more prolonged. It is difficult to lay down hard and fast rules such as a definite length of history beyond which operation should be advised automatically. Patients vary considerably in the periodicity of their ulcer dyspepsia, and any individual patient may himself vary in the frequency and severity of relapses from year to year. The majority of duodenal ulcer patients coming to operation have had symptoms for between 5 and 10 years,^{12 13} and an appreciable proportion have a history going back more than 20 years. Factors other than simply the length of time over which symptoms have persisted are generally taken into consideration in reaching a decision for operation in a particular patient.

When a patient complains that antacids, which formerly gave satisfactory relief, are no longer effective it seems reasonable to consider operative treatment without undue delay even if the history is relatively short. It is unreasonable to insist on waiting a fixed period of time if the patient has tried a large variety of antacid medications in adequate dosage without obtaining pain relief. On the other hand, the patient who enjoys long remissions of up to a year at a time and can fairly readily control his relapses when they occur by a simple antacid preparation may well not be advised to have surgical treatment unless some complication develops.

Loss of time from work through ulcer symptoms is another major factor, and this applies mainly to young and middle-aged men with families dependent on their continuing in regular employment. In the case of housewives symptoms interfering with their ability to perform their full household duties will also usually influence the decision towards operation. Repeated interruption of sleep by typical ulcer pain is yet another factor which might influence a decision towards surgery. When the pain begins to radiate through to the back this generally denotes a fairly severe ulcer with perhaps retroperitoneal penetration, and it is likely that surgical measures will eventually be required. Vomiting, particularly of a retention nature, suggests that pyloric stenosis is occurring, and again would usually be taken to favour operation. It is often remarkable, however, how a few days' rest in bed may allow the signs of "pyloric

stenosis" to subside, with cessation of vomiting, the disappearance of an obvious succussion splash, and shrinkage of the gastric outline on radiological examination.

Where there is a strong family history of peptic ulceration, particularly in the patient's immediate relatives, there is again a strong likelihood that operation will eventually be required, and a decision for surgical treatment may well be taken earlier than in those without such a strong family history.

It is difficult to assess the risks of complications such as perforation or haemorrhage in an individual case, but there is some evidence that patients with a previous history of haematemesis or melaena may be more prone to recurrence of this symptom. Between 30 and 50% of patients with a previous perforation of a duodenal ulcer treated by simple suture are likely to require later definitive surgery for the ulcer. There is therefore good reason to take the occurrence of either complication in the history of the patient with duodenal ulcer as being additional factors tending in favour of operation.

The question of malignant change only enters into consideration in the case of gastric ulcer, for it is virtually unknown for a chronic duodenal ulcer to become malignant.

Finally, with regard to blood groups it has been indicated that patients of blood group O, particularly those who are unable to secrete the blood group secretor substances in the gastric mucus, are slightly more likely to require surgical treatment than those belonging to other groups. However, there is recent evidence¹⁴ that group O non-secretor subjects are also more prone to develop stomal ulceration; so that if such patients are operated on they also have a slightly increased risk of further peptic ulcer trouble. In view of this confusing picture the blood group status should not influence the decision.

Risks of Operation

Every operation (like every form of effective medical therapy) is attended by some measure of risk of complication, and when advising a patient to undergo operation it is well to assess whether the severity of the disability caused by the ulcer is sufficient to justify the small but distinct risks. The mortality of an elective procedure for an essentially benign condition should nowadays generally be small, preferably less than 1%, though it is difficult to emulate the complete lack of operative deaths recorded from the admirable series of Goligher *et al.*¹⁵ In addition, a minority of patients may develop one of the variety of postoperative symptoms or symptom-complexes known to occur after all types of gastric operation. Fortunately the incidence of postoperative sequelae is quite small. Many subside with the passage of time or are controlled by simple measures, but a hard core may require repeated and complex therapeutic measures. Although some of the postoperative sequelae have a readily explained organic physiological basis, there is a distinct impression that patients with minimal history of symptoms, and those with signs of emotional instability pre-

* Senior Lecturer in Surgery, University of Glasgow.

operatively may be particularly prone to these postsurgical symptoms. For this reason surgeons generally are more confident about a trouble-free convalescence in ulcer patients having elective operation with a long severe history of dyspepsia behind them, and are perhaps a little more reluctant to accept for surgery patients showing signs of psychological abnormality. There is currently much interest in trying to assess personality and other psychometric measurements in duodenal ulcer patients in the hope that some more objective guide may be available to aid in this aspect of preoperative selection.

Type of Operation

The common aim of most elective operations for duodenal ulcer is permanently to reduce the capacity of the stomach to secrete acid and pepsin, in the belief that the hypersecretion of these substances is causally related to the ulcer. In spite of much indirect evidence this assumption remains unproved, and it may well be that the hypersecretion is simply a reflection of the underlying pathological mechanism which has caused the ulcer rather than that acid-activated pepsin has actually initiated the ulcerative process. There is no doubt, however, that in the vast majority of instances the measures taken to reduce the acid and pepsin secretion do result in healing of the ulcer and protection against further ulceration. Extending the argument that hypersecretion is an aetiological factor, there is considerable evidence that the excess secretion is vagally mediated, and for this reason vagotomy with a simple drainage procedure is currently in vogue as the elective operation of choice of many surgeons. The operative mortality seems to be acceptably low, but the incidence of recurrent ulcer is certainly higher than following gastric resection. The majority of these recurrences—if not all of them—are due to the vagotomy being incomplete, and this is perhaps the most important obstacle to the uniform acceptance of vagotomy. A drainage procedure is required to accompany vagotomy since vagal denervation alone has been found to lead to undue gastric stasis and vomiting. The two procedures most widely employed are gastrojejunostomy and pyloroplasty. Although theoretically the latter might seem a more sound physiological procedure, it is not as yet apparent whether one holds distinct advantages over the other. Perhaps the most widely discussed complication to follow vagotomy is diarrhoea. There is great variation in the reported occurrence of this symptom and its severity in different series. Most surgeons find that although there is a general tendency towards increasingly frequent bowel motions following vagotomy with drainage this amounts to disability only in a very small proportion of patients.

In an attempt to avoid vagal denervation of abdominal organs other than the stomach, various forms of "selective" vagotomy have been introduced in recent years. Claims that these procedures give adequate protection against recurrent ulceration, and diminish the incidence of other sequelae, require confirmation from further careful studies.

Adequate reduction of gastric acid and pepsin secretion can also be achieved by partial gastrectomy, and though published reports show a higher mortality rate than that of vagotomy with drainage this form of operation is less likely to be followed by a recurrent ulcer. The principal complications which may follow gastrectomy include nutritional disorders such as weight loss, steatorrhoea, protein and vitamin malabsorption, haematological defects such as iron deficiency and megaloblastic anaemia, "dumping symptoms," such as postprandial epigastric fullness, fainting, sweating, dizziness, and the desire to lie down, and bilious vomiting. The more incapacitating symptoms of the dumping syndrome and bilious vomiting fortunately occur in only a small proportion of gastrectomized patients, but the management problems they present are often extremely difficult ones. Long-term follow-ups of substantial numbers of

post-gastrectomy patients reveal a fairly high incidence of iron-deficiency anaemia and bone disorders, the signs of which often develop clinically many years after the operation.

It is still a little early to be certain about the incidence of these latter abnormalities following the simpler procedure of vagotomy with drainage, but the few preliminary reports which are available suggest that this operation may not be entirely free of such late sequelae.

The combination of vagotomy with a limited partial gastrectomy has been used in several surgical centres in the hope that removal of both the vagal and gastrin influences on gastric secretion might give greater protection against recurrent ulceration than either procedure alone. It was also hoped that with the relatively small proportion of stomach removed there be reduced chance of the troublesome postoperative sequelae met with after a more radical gastrectomy. Certainly the reported recurrent ulcer rates following this combined operation are encouragingly small. However, the mortality rate as might be expected lies intermediate between that of vagotomy with the simple drainage procedure and partial gastrectomy, and it remains to be seen whether the occurrence of postoperative sequelae will be substantially less than from either of the other two more commonly employed procedures.

One final word should be said about the management of patients once the elective operation has been performed. In spite of the rather long list of complications which may follow the various operative procedures it should be emphasized that they occur in but a small minority, and the majority of patients are able to eat normally for the remainder of their lives without fear of return of ulcer or other symptoms. They should be advised after operation that further dietary restrictions are unnecessary and that they should plan to return to a normal daily routine.

MEDICINE TODAY

Low Back Pain

"Medicine Today" is the television series for doctors produced by the B.B.C. Advice on the preparation of the programme is given by the Association for the Study of Medical Education.

The programme on B.B.C.2 on 7 November was on the subject of low back pain. Printed below is an article prepared with the help of expert contributors to complement the television programme, which will be repeated on B.B.C.1 on 15 November at about 11 p.m.

In "Medicine Today" much of the programme was devoted to the diagnosis and management of the acute lumbar disc lesion causing pressure on the sciatic roots. Though these cases form only a small proportion of patients presenting in general practice with low back pain, the signs and symptoms of the acute disc protrusion are so clear cut that the diagnosis is rarely if ever in doubt.

The patient is usually a young or middle-aged adult male who gives a clear history of acute disabling pain following an episode of bending or lifting, usually in an "awkward" position. The pain is confined to the lumbar region initially, but within 24 to 48 hours it spreads to one or other buttock and then down the back of the thigh to the outside of the leg and as far as the outer border of the foot. There may be associated numbness or paraesthesiae and the patient often has difficulty in walking even a few steps. The pain is usually relieved by lying down flat but made worse by sitting down. Coughing and sneezing make the pain worse and it is often impossible for the patient to bend his back.

On examination the patient is found to have a flat lumbar spine with obliteration of the normal lordosis, and he usually has a so-called "sciatic scoliosis" or a list to the side opposite to the sciatica. Spinal movements other than forward flexion are often surprisingly well preserved. The hip movements are full, but when the leg is raised with the knee extended pain is produced in the back of the thigh and the leg after about 15–30° of hip flexion. If the hip is bent forward or the knee is forced into dorsiflexion an increase in pain occurs (Lasègue's sign). There is often numbness to light touch and pinprick in the L5 or S1 dermatome. The extensor hallucis longus, the tibialis anterior, or the peronei are often weak and may be wasted, and the ankle jerk is usually depressed. In addition there may be gluteal flattening on the affected side.

Treatment of the Acute Disc Lesion

The essential feature of treatment is rest in a non-weight-bearing position—in bed on a firm mattress. Some 90–95% of patients with acute disc lesions will get better on this regimen, which should be succeeded by a period of partial immobilization in a plaster jacket or a well-fitting lumbar support. Instruction should be given in spinal and abdominal exercises. It is important at this stage that the exercises should be designed and graded so as to reproduce the degree of activity to which the patient will be exposed at work or home.

Patients who do not respond to this treatment may well benefit from alternative but infrequently used conservative measures such as rest in bed on continuous pelvic or skin traction. Others may respond to extradural injections of a local anaesthetic with or without a local corticosteroid. For the remaining few laminectomy may be the treatment of choice, but discussion of the criteria on which this decision depends is outside the scope of this article.

Pain not Associated with Signs of Nerve Root Pressure

The nature of the pathological processes responsible for pain in the back not due to disc lesions is the subject of considerable debate and contention. Advice on management of patients can be based on their classification into groups with common symptomatology. The treatment that is given for these conditions is essentially empirical.

"Acute Lumbago Syndrome"

Acute lumbago is characterized by a sudden onset of severe pain in the back precipitated by minor trauma or unaccustomed exercise. There is often radiation of the pain into both legs as far as the mid-thigh. A striking feature is that with the best will in the world the patient cannot get out of bed and indeed can hardly move at all. Though spinal movements are grossly reduced there are no abnormal neurological signs. The pain is relieved if the patient lies on a hard flat surface, and analgesics such as salicylates are very effective. No treatment other than rest and analgesics is needed. It is important that the patient rests completely for ten days and then mobilizes himself for another four to seven days. Simple back exercises at home and correct instruction in lifting technique are once again important during the "healing stage," which is generally complete within a few weeks from the onset. Further attacks are not uncommon but they are usually infrequent—one or two attacks every year or so.

The aetiology of "acute lumbago" is arguable, but if the initial attack is treated inadequately, by allowing the patient up too soon, then signs of root pressure may develop. This suggests that possibly the syndrome is an acute disc lesion of some type.

Pseudo-sciatica

This term is used to describe those patients who experience a sudden attack of pain—once again after minor trauma—but in whom the pain originates in the region of one or other sacral triangle and radiates down the back of the corresponding thigh, often as far as the back of the knee. There is no limitation of movement of the lumbar spine and straight leg raising is not limited to more than 45–60°.

These patients respond very satisfactorily to a variety of treatments, including manipulation; a gentle forced rotation of the pelvis with the unaffected lower limb flexed and rotated internally often produces dramatic relief. Relief may also be given by an injection of a local corticosteroid into the tender area that can almost always be found just medial to the sacroiliac joint. This syndrome seems to have a great deal in common with the musculotendinous disorders, of which tennis elbow is perhaps the best known.

Spondylolysis

Stress fracture of the pars interarticularis of one of the lumbar vertebrae is becoming increasingly recognized as a cause of pain in the back. It is a common finding in patients who present with a history of acute pain, not disabling, associated with a definite episode of feeling "something go" in the back. The signs on examination are pain at the extremes of flexion and extension and tenderness on deep palpation at the level of the lesion. Treatment of this condition is simple. Analgesics should be given as required and the patient should wear a simple

lumbar spine support for two or three months and then discard it. The fractures usually heal within two or three months, but though a few do not unite symptoms disappear after the initial period of pain.

Lumbar Spondylarthrosis

Degenerative changes in the spine are common findings in middle-aged and elderly patients with acute or chronic pain in the back. Spondylarthrosis is essentially an "x-ray diagnosis," but the radiological changes often bear little relationship to the degree of discomfort. In general, the grosser the changes shown the less is the range of spinal movement found on examination. Treatment of patients in this group depends not on the radiological findings but on the presenting signs and symptoms. Other relevant factors are the age, sex, and occupation of the patient, the length of the history, and such variables as the treatment that has been given in the past and its effect. The patient's personality, intelligence, and pain threshold are also important.

Acute episodes of pain are best managed at first by immobilization. After bed rest for a few days the patient should be encouraged to get up and about. A simple type of lumbar spine support, such as a canvas one, may be helpful at this time. Less severe pain is often best treated with immediate mobilization—exercises, physiotherapy, hydrotherapy, or even gentle spinal mobilization by manipulation without anaesthetic through the painfree range. Many patients with chronic pain in the back benefit from simple non-addictive analgesics, and these are best given in intermittent courses. The more powerful analgesics, such as phenylbutazone and indomethacin, can also be of great benefit at times, but they too should be given for short periods only.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Habituation to Methaqualone

Q.—What can be done to cure a patient of the habit of taking methaqualone tablets 150 mg. in quantities of up to 100 tablets a week? The drug was originally given for alcoholism.

A.—Methaqualone hydrochloride, or 3,4-dihydro-2-methyl-4-oxo-3-o-tolylquinazoline hydrochloride, is a sedative-hypnotic available in Britain as Melsedin (Boots) 150 mg., and Mandrax (Roussel) 250 mg. with 25 mg. of diphenhydramine. Addiction to this drug has been reported previously,^{1,2} and the withdrawal syndrome includes delirium tremens and abnormal states of muscular tone, though this is not inevitable.³

The patient referred to provides evidence of drug dependence of the methaqualone type, and, despite our lack of experience with it, it would be wise to view the condition with the same seriousness as one would a case of severe dependence on barbiturate, alcohol, or other sedative-hypnotic. The patient should be warned that this drug is equally likely to prove destructively addictive as more familiar hypnotics, and every effort be made to have him admitted as a voluntary patient to a psychiatric unit which specializes in drug dependence. Withdrawal can be undertaken

while a careful watch is kept for the first signs of convulsions, delirium, and appropriate drug therapy may be instituted at once in order to minimize harm. A prolonged period of physical and psychological support and rehabilitation may well be needed before the patient returns to normal living.

It is to be wondered whether the alleged value of methaqualone outweighs its addictive potential.

Rendu-Osler-Weber Syndrome

Q.—Oestrogen treatment of haemorrhagic telangiectasia has been suggested for a young woman who gets two or three nose bleeds a day from this. However, she is taking an oral contraceptive and refuses to discontinue it. Is there any way round this problem?

A.—The use of oestrogens in Rendu-Osler-Weber syndrome, as advocated by

Supportive Treatment

Many patients with lumbar spondylarthrosis are overweight. It may be difficult for the doctor to persuade the patient to slim, but this is important. Poor posture is usually attributable to environmental factors such as unsuitable seating arrangements at work, at home, or in the motor car. Considerable relief of symptoms can result from changes in the patient's environment with co-operation from the employer when this is relevant.

Understandably, some patients with backache of organic cause develop a degree of reactive depression or anxiety. This may be helped by simple psychotherapeutic measures, or treatment with tranquillizers or antidepressives may be necessary.

Non-organic Low Back Pain

When all else has been excluded there remain the patients with backache for which the most extensive investigation reveals no organic cause. Many of these patients are suffering from a depressive illness with somatic conversion symptoms, for which other evidence may be sought. They respond totally and dramatically to a therapeutic trial of anti-depressive drugs, such as amitriptyline 50 mg. t.d.s. or imipramine 25–75 mg. t.d.s. These drugs produce their effect within two to four weeks, and the response in some patients with low back pain which may have persisted for years can be astonishing.

Finally, it must not be forgotten that a number of serious life-threatening conditions may present as acute back pain. These include spinal and extraspinal tumours either primary or secondary, tuberculosis, and other infections. Occasionally intra-abdominal conditions such as peptic ulceration or even acute pancreatitis may present as an "acute back." A careful history and a full clinical examination should never be omitted.

Harrison,¹ has enjoyed a modest success in this country. The elastic and muscular coats of the vascular sinuses are absent, and for that reason it is unlikely that the effect of the oestrogen is directly upon the blood vessel. Its haemostatic effect must therefore be due to the general thickening of the mucus membrane induced by the oestrogens.

All the oral contraceptives sold in this country contain either a potent oestrogen (mestranol) or else break down metabolically to yield oestrogens themselves. The dosage of oestrogen, generally about mestranol 0.1 mg. per day, is enough to exert a maximum oestrogen effect on the mucus membranes. It is unlikely, therefore, that any further benefit would be derived from additional or alternative oestrogens. The patient could perhaps be persuaded to switch to the sequential type of oral contraceptive, which would have the advantage of avoiding any progestational effect at least during the first fortnight of her cycle.

A number of alternatives to oestrogen therapy are available. Saunders² has described an ingenious form of septal dermoplasty. Stewart³ has advocated the use of deep x-ray radiation; while Golding-Wood⁴ found transantral internal maxillary ligation to be of benefit, particularly when combined with zinc ionization.

Get to the point

IN SINUSITIS, OTITIS MEDIA AND TONSILLITIS...

Mycivin gets right to the point of infection and acts swiftly... decisively.

Mycivin has a unique range of activity against the Gram-positive pathogens commonly present during

infections of the respiratory tract, bone and soft tissue.

Mycivin is highly active against streptococci, pneumococci and staphylococci — including many

strains resistant to other antibiotics.

Mycivin is the chemically distinct antibiotic lincomycin; available as capsules, syrup and ampoules (as the hydrochloride monohydrate).

Book Reviews

Man's Pollution of the Earth

Pesticides and Pollution. The New Naturalist Series. By Kenneth Mellanby. (Pp. 221; illustrated. 30s.) London: Collins. 1967.

Civilized man is the only unnatural animal. He manipulates his environment to reduce mortality in the youngest and to prolong life in the oldest, and even when he dies he does not surrender his carcass to the natural processes of putrefaction—it either goes up in smoke or deep down in the sterile clay. He cannot live without producing waste products from his body, but he goes to vast trouble to make sure that these are used, not to enrich the soil, but to foul the waters. He is not prepared to accept the climate as he finds it, but uses fire to adjust surrounding temperatures to his liking, and in the process forces enormous clouds of grit and gases into air that would otherwise be clean and pure. He scorns to move over the earth as fast as his own two legs will carry him, but races instead on wheeled contraptions which emit poisonous fumes as he rushes along. When he has time to stop, he is not content to eat the fruits of the natural earth, but rips and tears the land with steel, and allows only those plants to grow that measure up to his demands. And if any herb defies him, or any insect attempts to share the food in his artificial fields, he drenches them with poison. *Homo sapiens* is a highly civilized being.

Kenneth Mellanby has written a great book. It is calm, logical, and dispassionate, but deeply moving and disturbing. When facts can be given with precision, he states

them. If he can explain them, he does so; if he cannot, he says so. The book is full of facts and figures—the amount of grit deposited on one square mile, or even one square yard, per year, the amount of oxygen required to break down the daily output of faeces of one human being, the concentration of insecticide found in the fat of an Adélie penguin in the Antarctic or of a business man in America. Many of these figures are startling, but they are not given in order to startle, but because they are part of the picture. Some other parts of the picture are much more startling because they depict things that we accept almost as "natural." Draining a marsh, for example, can have a much more disastrous effect on wild life than the most poisonous chemical, and a day's ploughing of a mature pasture may exterminate a population of earthworms built up over 70 years. Traditional agriculture has, in fact, catastrophic effects on the ecology of the area in which it is practised.

Man must control his environment if he is to survive in it. Unfortunately he often cannot foresee the final result of a process which at first is obviously beneficial. Dieldrin used as a sheep dip freed the animals from the plague of fly strike; but eagles feeding on sheep carrion in the Western Highlands were poisoned, and the poison was found in their unhatched eggs. D.D.T.

(not D.D.T.) was used very successfully for midge control on Clear Lake in California; the poison was taken up and concentrated in the tissues of tiny fish, then in the tissues of larger fish that ate them, and finally, at the end of the food-chain, it killed the water birds that dived into the lake for the big fish. But death may not be the worst remote effect of chemicals used to destroy life. Genetic changes might conceivably be caused in birds or animals or in man himself. Dr. Mellanby thinks this is most unlikely, but he points out how the dangers of radiation proved far greater than the experts expected. It is difficult to find in Britain a field, an animal, or a bird without trace of pesticide, and no one can tell what the effect in 20 years may be.

This book deals with an immense problem—man's pollution of the planet he lives on. It is written with immense understanding and immense fairness. It makes fascinating, absorbing reading. The author states that an informed public opinion is essential if the problems of pollution are to be tackled intelligently. His book gives the public the necessary information and should be read by every person with enough intelligence to realize that there are such problems. The book is excellently produced, and very few errors have escaped the proof-readers, but although Dr. Mellanby writes with an easy charm, "conversationist" on page 60 is almost certainly a misprint for conservationist. The photographs vividly illustrate the text. The book will have a wide circulation and will stimulate and disturb every thoughtful reader.

A. B. CHRISTIE.

Symposium on Renal Dialysis

Replacement of Renal Function. Proceedings of the European Dialysis and Transplant Association. 1966. Vol. 3. Edited by David N. S. Kerr. (Pp. 400+xxiii; illustrated. £7 10s. 9d.) Amsterdam: Excerpta Medica. 1967.

A wide variety of papers were read at this conference ranging over the whole field of dialysis, but with a relative neglect of transplantation. The articles are published in either English or French, but unfortunately most of those in French do not have English summaries. The main section of the book consists of papers. This is followed by a report of the demonstrations shown at the conference.

Knowledge of the incidence of uraemia in the population is very important in order to assess the requirements of dialysis and transplantation. J. H. Thaysen (Denmark) estimated that there were 200 deaths per million per year in Denmark. Relating these deaths to costs at the present time S. Shaldon considers that hospital dialysis capital costs are £2,000 per annum and £2,070 a year running costs, as opposed to a capital cost of £3,500

for home dialysis and £1,210 running costs. Both N. H. Scribner and Shaldon agreed that home dialysis is preferable to hospital dialysis. It will be cheaper in the future and the patient relies on himself rather than becoming dependent on an institution. They consider that dialysis should be started early before the severe complications of uraemia such as peripheral neuritis and pericarditis become established.

W. Drukker and colleagues reviewed the European experience with recurrent dialysis. There was a mortality rate of 40% in the first six months, 33% in the second six months, 26% in the second year, and 20% in the third year. This confirmed the high rate of early complications. One of the most serious problems was the development of hepatitis occurring in dialysis units. In 19 centres there had been 40 cases of hepatitis, with four deaths occurring among patients and four deaths among staff. These rather depressing pooled results were in marked contrast to the most experienced centres, Shaldon in particular having had no deaths in the course of a year's programme of haemodialysis.

It used to be felt that with clinical recovery from acute tubular necrosis renal function

was restored to normal, but there is now an increasing amount of evidence that many patients do suffer residual renal damage. A. C. Kennedy and colleagues reported that 72% of patients recovering from acute tubular necrosis have diminished renal function, the most common abnormality being diminished glomerular filtration rate.

J. P. Merrill discussed the relation to haemodialysis of renal transplantation, and pointed out that there was no evidence from the results at the Peter Bent Brigham Hospital that prolonged haemodialysis sensitizes patients against subsequent renal transplants. This was interesting and perhaps rather unexpected. It is perhaps not impossible that some type of "desensitization" against human tissue antigens had taken place after multiple blood transfusions.

In general the discussion following the papers is interesting and constructive, and several sound points are made by "unidentified members." This volume can be recommended to all interested in haemodialysis, but those expecting to obtain up-to-date information on renal transplantation will be disappointed.

R. Y. CALNE,

Parkinsonism

Parkinson's Disease. By Leslie Oliver, M.B., B.S., F.R.C.S., F.A.C.S. (Pp. 69; illustrated. 21s.) London: William Heinemann, 1967.

With the development of new techniques, and the ability to offer hope of some new measure of relief to those who are suffering from Parkinsonism, there is a demand to know more about the present position as regards the medical and surgical treatment of the disease. This book is a communication from an expert on the subject, intended to give information to those whose work lies in other areas of medicine. It is not meant to be a textbook or work of reference for neurologists and neurosurgeons for whom the detail is inadequate, but is a small monograph in which the history and pathology of Parkinson's disease are briefly described, the medical armamentarium is summarized, and modern surgical treatment is reviewed.

The book will certainly be of interest to general practitioners and general physicians, and to nurses, physiotherapists, and social workers, who are required to collaborate in the care and management of these patients. It is therefore a pity that the social and psychological problems confronting the sufferers and their relatives are not given as much attention as they deserve. A small illustrated chapter might have been devoted to hints at the means of overcoming some of the commoner difficulties.

Those who are not surgeons are nevertheless concerned to know what aspects of this very protean condition are most likely to be helped by surgery, and to know equally precisely the contraindications to operation, the extent of benefit which may be hoped for, and the future which lies ahead. Most of this information is to be found in the book, but reference would be easier if it was brought together. Many pages are devoted to description of the operative technique favoured by the author, and other methods receive rather scant mention. As the book is likely to be referred to by nurses and radiographers, most of whom will be working with a variety of instruments, it would have been beneficial to limit the operative detail to a more concise presentation, and replace it by line drawings or photographs of one or two alternative methods and types of apparatus.

The book is to be welcomed, but it is hoped that in a future edition its usefulness will be extended.

PETER H. SCHURR.

Laparoscopy

Laparoscopy in Gynaecology. By Patrick C. Steptoe, F.R.C.S.(Edin.), F.R.C.O.G. (Pp. 92 + viii; illustrated. 40s.) Edinburgh and London: E. & S. Livingstone. 1967.

This book is a complete guide to the use of laparoscopy in gynaecological practice. The author believes that endoscopic examination of the pelvic organs by the trans-peritoneal route can give similar information to that obtained at laparotomy, and allow as detailed an examination of these organs as is now routinely applied to the vagina and cervix.

There are 16 chapters. A brief historical review is followed by more detailed chapters

on modern cold light instruments and abdominal and vaginal techniques, the author preferring the former. Indications, contraindications, and possible complications are discussed, and there are chapters on laparoscopy in the diagnosis of unruptured ectopic pregnancy, sterility and amenorrhoea, and ovarian dystrophies. The style is factual and concise and the text is so liberally illustrated by diagrams and photographs that technical points are readily understood. Of special interest to surgeons contemplating the procedure are 24 laparoscopic colour photographs of pelvic diseases.

As experience is gained in laparoscopy it is possible to perform sterilization and ventrosuspension operations in addition to biopsy, division of adhesions, and aspiration of cysts. Full details of these operations are given. The aspiration of small ovarian cysts later proved malignant may allow an early diagnosis, but seems not without risk.

There are obvious advantages for the patient in laparoscopy, if laparotomy is not subsequently required. This monograph may convince many non-believers that there is now a place for laparoscopy in gynaecology. The author is convinced of its safety and believes it an essential technique for the modern gynaecologist.

D. L. MORRISON.

Essential Information on Tropical Problems

Clinical Tropical Diseases. 4th edition. By A. R. D. Adams and B. G. Maegraith. (Pp. 582 + x; illustrated. 70s.) Oxford: Blackwell. 1966.

Since it was first published in 1953 this book has reached its fourth edition, and this in itself testifies to the need it satisfies. In this edition many useful revisions have been made, some new material has been introduced, and other parts have been brought up to date, yet it is still near its original size. The first edition contained 508 pages, and this one has increased to only 582; it remains therefore of medium size and eminently portable. The aim has continued since the book was first published to give information essential for clinical diagnosis and treatment dogmatically and concisely, avoiding speculation, and making no attempt to provide information of an encyclopaedic nature. These aims have been well maintained.

Among the new material there is an excellent section on glucose-6-phosphate dehydrogenase deficiency, and the new schistosomicide niridazole (Ambilhar) has received attention. The new developments concerning cholera and the remarkable spread of the El Tor vibrio receive prominence; there is a section on kuru, and snake-bite has been extensively revised. In the new writing the high standard set by the earlier editions has been well maintained.

The book continues to be one which the doctor in the tropics, the student of tropical medicine, and the physician in temperate climates who occasionally is confronted with tropical problems can turn to with confidence. He knows that it is authoritative, up to date, and that in it he will find essential information concisely presented.

A. W. WOODRUFF.

World Federation for Mental Health

Reflections. A Personal History and an Account of the Growth of the World Federation for Mental Health. By Dr. John R. Rees. (Pp. 178 + xxviii. \$10.00. Autographed de luxe edition \$25.00.) New York: World Federation for Mental Health. 1966.

In the subtitle of this book it is called a "Personal History"; it might therefore be expected to show the usual characteristics of autobiography, in which egotism is commonly rampant. Seldom, however, can an autobiography have shown more freedom from self-justification and display—the Little Jack Horner syndrome—than this modest record of altruistic effort. It is mainly a factual chronicle of the growth of the World Federation for Mental Health, as the second half of its subtitle indicates. Dr. Rees says in one passage that he had the privilege of visiting nearly 70 countries in the course of his work as director. Viewed from another standpoint this can be seen as evidence of the demands made upon him, which he met without regard for personal convenience.

In a tribute based upon years of close association and friendship, Dr. Brock Chisholm, former Director of the World Health Organization, says, "I have sometimes felt irritated by J.R.'s attitude, but always by what I felt was an excess of tolerance"; and he rightly adds that it is hard to distinguish between Dr. Rees's tolerance and his "pervasive love of humanity as individuals." His warm-hearted liking for all kinds of people, and his generous appreciation of what they can contribute to the common good, have obviously been powerful factors in his success in guiding three exacting organizations. He was medical director of the Tavistock Clinic, consultant psychiatrist to the Army, and director of the World Federation for Mental Health.

The book, which has forewords from intimate associates of Dr. Rees, relates the stages through which the World Federation for Mental Health has passed from its inception in 1948 to its present widespread activity. The achievements of this organization in kindling interest and stimulating organizations and governments to promote mental health have been, to a very large extent, due to the efforts of the self-effacing, resilient psychiatrist who acted for 15 years as its moving spirit.

AUBREY LEWIS.

Advice for the House-surgeon

Manual of Preoperative and Postoperative Care. By the Committee on Pre- and Post-operative Care, American College of Surgeons. Editorial Subcommittee: Henry T. Randall, M.D., James D. Hardy, M.D., and Francis D. Moore, M.D. (Pp. 506 + xiv; illustrated. £2 19s. 6d.) London: W. B. Saunders. 1967.

The newly qualified house-surgeon of today faces not only the routine note-keeping on his patients and assisting his chief in the operating theatre but also the increasingly complex problems of handling the metabolic and nutritional disturbances of major surgery.

With this in mind the present volume has been prepared by the Committee on Pre- and Postoperative Care of the American College of Surgeons. It is designed to provide a quick and concise account of recent advances in surgical metabolism and nutrition.

It therefore covers first the topics of fluid and electrolyte balance, the physiological changes of surgical stress, clotting disorders, infection, and shock. In the later chapters of the book methods of handling the pre- and post-operative care of patients undergoing surgery of the major body systems are considered, and these include the management of their common complications and of surgical emergencies. As well as general surgical considerations, cardiac, gynaecological, urological, and orthopaedic problems are considered together with a chapter on the management of burns. Useful appendices include data on laboratory tests and diets. The individual chapters have been prepared by a total of 29 surgeons, many of whom are well-known names on this side of the Atlantic. Particular mention must be made of Dr. Francis Moore, who is not only one of the editors but who also contributes an important chapter on metabolic response to injury and another on surgical nutrition.

This book will certainly prove of value to the hospital resident junior staff. The text reads easily and combines practical advice with adequate and up-to-date theoretical background. Most chapters have useful bibliographies. Here and there one detects difference in practice between the two sides of the Atlantic in, for example, the advice to discuss the cost of treatment with the patient. In most respects, however, this book covers the needs of the British house-surgeon equally as much as his American intern counterpart.

HAROLD ELLIS.

Looking after Students' Health

Student Health Services in Great Britain and Northern Ireland. By Professor Alex Mair. (Pp. 236+xii. 42s.) Oxford: Pergamon, 1967.

This is a disappointing book. Despite the fact that student health services have existed for several decades in the U.K. and overseas, there is considerable confusion and lack of knowledge about them. The administrative, medical, and psychiatric problems and the complexities of this kind of work are ill-understood among both university personnel and doctors generally. There is thus a real need for comprehensive, accurate, up-to-date, and detailed information, and for discussion of some of the critical issues.

Professor Mair has attempted to tackle the problem on the basis of replies to questionnaires circulated in 1960. The result cannot fairly be described as "a comprehensive account of what the student health service is in Britain today." It is a piecemeal assortment of data, much of which is manifestly obsolescent, and in respect of services introduced since that time non-existent. The services of, for example, London (City University), London (Central Institution), Sussex University, and Birmingham (Aston) are not mentioned.

The contents of the book naturally reflect the kind of questions asked in the questionnaire. Readers expecting to find discussion of topical issues of major importance in student health work, such as late adolescent development, learning problems, unwanted pregnancy and contraception, and drug-taking, will search in vain.

Professor Mair is an advocate of a preventive approach on the lines of school or industrial services, rather than the compre-

hensive service which attempts to accept full treatment responsibility for individual students. In this he differs from the 1966 report of the Royal College of Physicians (the earlier reports only are referred to in the book) and with the consensus view in the British Student Health Association. The particular difficulties of adopting a preventive approach in relation to mental health—in which prevention in this setting mainly means early identification followed by skilled management—are not fully discussed. Indeed, little impression of this type of activity can be gathered from the book; counselling is equated with guidance and reassurance, though we are told that it is "time-consuming if done thoroughly."

Other aspects of preventive work receive more thorough consideration, although there is little about environmental safety, accident prevention, and laboratory safety, and the possible role of a safety officer in the university.

Some points, well and strongly made, certainly deserve the emphasis the author gives them. For example, his point that no student should leave for reasons of academic failure without the fullest investigation of his mental and social well-being is extremely important. How often is this attempted in British universities today? He also argues that services should be university services covering all members of the community, rather than student health services—a view which most of those working in the services would endorse, given that sufficient support could be obtained.

In conclusion, this is a book with many shortcomings, but nevertheless it does contain a great deal of information and raises many points. It will certainly prove a controversial work which will be widely read and discussed.

CHRISTOPHER J. LUCAS.

IN CO-OPERATION WITH THE NATIONAL COUNCIL ON ALCOHOLISM AND THE GLASGOW, GLOUCESTER, AND LIVERPOOL
ALCOHOLISM INFORMATION CENTRES

Brit. med. J., 1967, 4, 346-349

In Britain alcoholism is a condition which causes embarrassment and perplexity. The alcoholic is often ashamed to seek help, and if he does want help he may be uncertain where to find it. The National Council on Alcoholism, a voluntary organization inaugurated in 1963, has sought to meet this problem by fostering the setting up of alcoholism information centres and has encouraged and assisted local community councils on alcoholism, in various parts of Britain, to open centres which break away from the rescue mission and "Skid Row" aura which so often clings to alcoholism. The centres have been set up in better and central areas of towns; furnishing and décor are of good quality and tend to suggest a modern office suite rather than a clinic. The policy has been to employ staff with wide practical experience of helping the alcoholic rather than to look for counsellors with professional training.

An important part of the job of a centre is that of making contact with the local community and by means of visits, talks, pamphlets, articles in local newspapers, etc., ensuring that the existence of the centres' services is widely known. The hours of opening vary from centre to centre. The aim is to provide help which is friendly, confidential, and immediate, and the door is open to the alcoholic, his spouse, the employer, or any other concerned person or agency. The work of the centres is seen as that of sorting out immediate problems, and directing toward help, rather than providing treatment or long-term counselling.

In 1966 the staff of the Alcohol Impact Project were approached by Colonel Peter Perfect, the executive officer of the National Council on Alcoholism, with the suggestion that the research team should carry out a survey of the work of the three longest-established centres.

Method.—A precoded structured questionnaire was evolved which could be used at an initial interview without interfering with the helping relationship. Staff of the Glasgow, Gloucester, and Liverpool centres then administered this questionnaire each to a consecutive series of 100 clients. The collection period differed slightly between the three centres, but averaged about four months. Data from the 300 completed schedules were analysed on the University of London's I.B.M. 7090 computer.

Of the 300 clients 264 were men and 36 were women. Data on the men are presented in detail, and results on the women are given more briefly.

* From the Alcohol Impact Project Addiction Research Unit, Institute of Psychiatry, Maudsley Hospital, London S.E.5.

Male Clients

Twenty-three per cent. of the male clients had been referred to the centre by a doctor, 20% were self-referred, 14% had been brought or sent along by the spouse or other member of the family, 9% had been referred by a probation officer, 5% had been brought along by a friend other than family member, and the remaining 29% had been referred from a wide variety of agencies, which include Alcoholics Anonymous, Family Welfare and Marriage Guidance, personnel officers, clergymen, etc.

The mean age was 43.1 years (S.D. 9.4). Forty-nine per cent. had been born in England, 39% in Scotland, 9% in Northern or Southern Ireland, and 2% in Wales; 1% gave other places of birth. Forty-eight per cent. of clients were married, 16% single, 24% separated, 9% divorced, and 3% widowed. Social class determined according to the Registrar-General's Classification (General Register Office, 1966) (Table I), shows that there has been a slight tendency toward downward drift.

TABLE I.—Male Clients: Socio-economic Class by Occupation

Class	"Best"	"Now"
I (professional)	6	6
II	22	18
III	48	41
IV	18	23
V (unskilled)	6	12

Eighty-six per cent. described a pattern of continuous drinking and 14% a pattern of bout drinking. Ninety per cent. of male clients had experienced "morning shakes," and 76% of these had been in the habit of taking a morning drink to relieve shakes. All but 5% had experienced amnesias for the previous evenings, and 37% had at some time attempted suicide.

Thirty-two per cent. had not been on a drunkenness charge, 51% had been convicted and fined only, 17% had been convicted and gaoled. Twenty-eight per cent. had been convicted of driving when drunk. Twenty-five per cent. had been in prison for offences which were not technically "drunkenness" offences but which the clients believed to be a direct consequence of their drinking.

Only 22% of clients believed their general practitioner to be unaware of the drinking problem. One per cent. had not seen a general practitioner during the previous year—56% had seen their doctor during the preceding month, 10% during the preceding one to two months, and 14% in the preceding two to

three months. Forty-four per cent. had personally sought help from their doctor, while 30% believed that the wife had consulted the doctor for assistance. However, 74% said that during the previous year they had attempted to "fool" a doctor, and had given false reasons for requiring a medical certificate.

Employment

At the time of interview only 50% were in full-time employment; 4% were in part-time employment, 13% off sick with a job to which to return, 32% unemployed, and 1% retired. That the working population under study consisted of others besides transients and casuals is suggested by the finding that 23% of clients had been with their present employer for less than six months, 15% for 6 to 12 months, 13% for one to two years, and 49% for more than two years. Further evidence on this point is the finding that only 5% of men gave less than one year as their longest period with one employer ever, while 65% gave more than five years as the longest period spent in one job.

The mean time off work for those sick or not employed at the time of interview was 6.5 months: the distribution was in fact skewed, with 75% of the non-working having been out of work for six months or less, and 25% having been out of work for periods ranging from six months to five years. When replies from the total sample of 264 men to a question on days lost from work due to drinking during the previous year were analysed it was found that only 2% stated that they had lost no time from work, and the average number of days lost during the year was 86 (S.D. 82). Only 10% thought that they had received any promotion at work during the previous five years, only 24% believed that drinking had not interfered with promotion, and 47% were in a lower-paid job than their immediately previous employment. Eleven per cent. were certain that during the previous year their drinking had contributed causally to an accident at work, while 32% thought that their drinking might in some way have been implicated in such an event. Seventy-five per cent. had at some time lost a job because of drinking and 12% had been sacked more than five times because of drinking. Thirty-eight per cent. had been dismissed because of the drinking during the immediately preceding year.

Many also gave a history of frequent lateness at work and Monday morning absenteeism due to drinking (Table II).

TABLE II.—*Male Clients: Frequency of Unpunctuality and Monday Morning Absenteeism During Previous Year*

Frequency	Late at Work %	Absent on Monday morning %
Never	9	7
Rarely—once or twice per year	20	27
Quite often—once or twice per month	44	40
Frequently—more than twice per month	22	21
Not applicable—unemployed, retired, etc. . .	5	5

Sixty-two per cent. stated that they had on occasion brought a bottle into work with them, and 12% were doing this every working day. Eighty-eight per cent. were at times having a drink before coming into work, and all but 9% said they could occasionally contrive to keep drinking throughout the working day.

Sixty-nine per cent. of male clients had during the previous year received some warning from their employers, and 59% had indeed been warned about their drinking more than once during that year. Fifty-two per cent. of men said they believed that the company had no consistent policy as regards drunkenness, a further 22% were unsure on this point, and only 26% felt they really knew where they stood. Fourteen per cent. said that the company simply ignored drinking. Fifty-eight per cent. of the clients stated that other employees in the firm had definitely lost a job because of drinking, while 53% had heard of fellow employees being warned. Where there was a com-

pany doctor—in 31% of instances there was no one holding this position—49% of clients said it would be impossible to consult him because of the drinking problem, 36% were unsure whether it would be wise, 11% felt it possible but had not done so, while 13% had indeed sought advice and help from this source.

During the preceding year 74% of clients had sought help from a general practitioner, 55% from a hospital, 44% from Alcoholics Anonymous, 26% from a probation officer, 25% from a minister of religion, and 21% from a marriage guidance counsellor.

Women Clients

The mean age of the women was 44.9 (S.D. 10.5)—not significantly older than for men. The distribution for place of birth and marital status closely resembled male distributions. The general impression is of less severe involvement in pathological drinking: 41% reported continuous drinking, 76% had experienced morning shakes (45% of these had been in the habit of taking a morning drink), and 12% had not experienced amnesias. The incidence of attempted suicide was similar—33%. Only 18% had been charged with a drunkenness offence, and half of these had been to gaol. None had been charged with drunken driving. Six per cent. had been in gaol for some other offence connected with drinking. Rather closer contact was being maintained with the general practitioner—76% had seen their doctor during the previous month. The number in employment was too small to allow any meaningful analysis of the impact of drinking on work. Women seem to seek help from much the same agencies as men.

Discussion

Did this study get at the truth? Proper caution is necessary before accepting any information given by alcoholics that has not been validated, but, if anything, the results probably err toward underestimating rather than overestimating the damage which drinking has done to these people's lives—a man is more likely to conceal the fact that he has been in prison than to invent a story that he has served a gaol sentence. With questions such as whether the general practitioner or employer knows of the client's drinking, or whether the firm has a consistent policy, what is being reported is simply what the client believes to be the case. Moreover, the interviewers were not trained research workers, though they had very considerable experience in talking to alcoholics and forming good and easy relationships, and the structured design of the questionnaire obviated many difficulties.

Who Comes to the Information Centres?

If the information centres are attracting anything like the "average" alcoholic, then our findings are a powerful corrective to the view that the ordinary alcoholic is a drifting down-and-out. The centre clients are quite different from those of London's Skid Row (Edwards *et al.*, 1966) (Table III). The social background of the person who comes to the alcoholism information centre closely approximates to that of the ordinary socially integrated citizen.

The demographic characteristics of men in this study may be compared with those of Alcoholics Anonymous members

TABLE III

	Information Centre	Skid Row
Semi-skilled or unskilled males	35%	88%
In one job for more than 5 years	65%	6%
Married or had been married at some time	84%	36%
Still married	48%	0%

(Edwards *et al.*, 1967) and patients attending a National Health Service hospital (Edwards and Guthrie, 1967).

This study also answers the question whether people who come to information centres are suffering from alcoholism of the same type and degree as those who go to doctors. By any definition the majority of clients of information centres are indeed "real" alcoholics. Ninety per cent. of the men studied here had suffered from morning shakes—a symptom which may be regarded as pathognomonic of severe alcohol dependence. The figure for Alcoholics Anonymous was 84%, for hospital patients 100%, and for Skid Row 92%.

Why do people go to an information centre? Why are they asking for help at all? The answer to this part of the question seems to be simple—these are people who are undergoing a great deal of suffering. We did not attempt to analyse the impact of their drinking on their physical or mental health, but that 37% of men and 33% of women have attempted suicide is some indication of the degree of social damage which is being undergone. Breakdown of marriage, entanglement with the law, and failure at work are some of the elements of chaos—the personal suffering of the alcoholic is not something to be forgotten in the statistics (Lowry, 1967). It would be too optimistic to suppose that the relative under-representation of subjects in the older age groups among clients of information centres is just explained by older people having generally got the treatment they required or having reverted to normal drinking (Davies, 1962; Kendell, 1965); it seems likely that this finding is in part a hint of the diminished life expectancy of the alcoholic.

The question why it is to the information centre that these alcoholics turned perhaps has its answer in the fact that the alcoholic who in this country today wants help can have a very frustrating time finding it. His confusion often seems equalled by the bafflement of those to whom he turns.

The frequency with which the alcoholic seeks to mislead his doctor when asking for a certificate illustrates another aspect of the confusion. Perhaps one reason why the information centres are attracting business is that this reflects the consequences of a system of medical training and qualifying examinations which put little stress on the understanding of personal problems and social distress.

Impact on Industry

The statement has recently been made that alcoholism is costing the country's industry millions of pounds a year (National Council on Alcoholism, 1965). Only very rough estimates of the number of alcoholics in Britain are available, but in 1948 the World Health Organization (1951) made a guess that there were about 350,000 alcoholics, 75,000 of them being "chronic alcoholics," in England and Wales. If the W.H.O. figure is even anywhere near correct, multiplying up the losses to industry caused by the 264 men attending the three information centres studied by a factor to give the total national impact of alcoholism on industry would suggest a quite astonishing figure. The cost to various welfare services would also be enormous. The findings that 50% of male clients were out of work at the time of interview, that 38% had been sacked because of their drinking in the previous year, that the average days missed from work during the preceding year was 86 days, that only 1.5% had not lost time from work during that year, the data on lateness and Monday morning absenteeism set out in Table II, all this suggests an industrial disease deserving the most urgent attention. Quite apart from actual time lost from work, there is the question of inefficiency while still at work: some measure of this aspect of the problem is suggested by the 76% who believed that their promotion has been blocked and by the 11% who say that they have caused accidents by their drinking, and inefficiency is hardly to be wondered at when 88% of clients were occasionally drinking

before work, 62% sometimes bringing in a bottle, and 90% sometimes drinking throughout the day. Quite terrifying risks are being taken.

As for sacking as a solution, the alcoholic will usually simply go and find another job, and take his unsolved problem with him. The State will for a period pay out some more sickness or unemployment money, and then another firm takes on the problem where it was left off. The 12% who have been sacked more than five times present extreme examples of this process of circulation.

Future of Information Centres

Besides their specific value in giving help to alcoholics, these information centres probably have a wider importance. They provide an interesting example of what must surely be the new trend in mental health, of the effort to reach out into the community rather than to sit back in the hospitals. In America the approach to drug addiction seems to be taking very much this direction.

There can be no doubt that information centres are reaching the alcoholic, but whether, having reached him, they are able to take appropriate action is another question. It would seem likely that workers in these centres, widely knowledgeable as they are about the networks of local referral systems and local availability of treatment resources, are providing an extremely useful service; but, in the end, the limit to what they can achieve is set by limits of availability of treatment and rehabilitation. Recently, after the most useful stimulus provided by a Ministry of Health (1962) memorandum, regional hospital boards have set up a number of special units for the treatment of the alcoholic: it is to be hoped that energetic community-orientated treatment services, coping with the needs of every type of alcoholic rather than with the few who can benefit from intensive inpatient psychotherapy, will now be developed on the basis of existing units, and on the basis too of the very considerable skill and experience gained by the staff who have been running these regional units.

When such community treatment services are developed, alcoholism information centres would clearly continue to play a very important part within them. Surely sooner or later the information centres must be given official and permanent financial backing rather than that their survival should depend largely on their ability to raise money from charity. The staff of these centres will also of course go on playing a valuable part as educators. Rational planning, education of the public, and better education of many specialist groups are all urgently needed if chaos is not to be perpetuated.

Summary

By the use of a structured questionnaire information was obtained on 100 clients attending each of three alcoholism information centres—Glasgow, Gloucester, and Liverpool.

People making use of these information centres are very largely citizens with a normal background of social integration—the lack of similarity with the Skid Row stereotype is stressed. Clients come to these centres because they are confused regarding where else to turn.

Besides their importance because of the service they are giving to alcoholics, these information centres are of wider significance in the example they provide of a "reaching-out" type of community approach to mental health.

Appendix: Location of Information Centres

Cardiff and District Council on Alcoholism and Drug Dependency, Dyfrig House, Fitzhamon Embankment, Cardiff (Tel.

32127). East Midlands Council on Alcoholism, The Dan'l Lambert, Albion Hill, Leicester. Glasgow Council on Alcoholism, 141 Bath Street, Glasgow C.2 (Tel. City 3111). Gloucester Council on Alcoholism, 11 Barton Street, Gloucester (Tel. 22682). London Alcoholism Information Centre, 25a Wincott Street, London S.E.11 (Tel. Rel 0456). Merseyside Council on Alcoholism, 14 "B" The Temple, Dale Street, Liverpool 2 (Tel. Central 0300 and 1372). Staffordshire Council on Alcoholism, 48 Greengate Street, Stafford. Centres are also currently being established in Edinburgh and Herefordshire.

We wish to thank Dr. D. L. Davies, Senior Director of the Alcohol Impact Project, for his continued encouragement. Our thanks are specially due to Colonel Peter Perfect and Miss E. M. Keys, of the National Council on Alcoholism, to the members of the Medical Committee of the N.C.A. (chairman at that time Dr. H. D. Chalke), who gave much help at the planning stage, and to the staff and directors of the three co-operating information centres—Mr. John

Gray (Glasgow), Mr. Michael Taylor (Gloucester), and Mrs. W. H. Kenyon (Liverpool). Mrs. Barbara Kinsley, Mr. Michael Clark, and Mrs. Hedi Firth kindly helped with statistical analysis. We thank Mrs. Julia Polglaze and Miss Ethane Cross for all their secretarial work. The study was supported by a grant from the Bethlem Maudsley Research Fund.

CONFERENCES AND MEETINGS

Uses of Niridazole

[FROM A SPECIAL CORRESPONDENT]

A conference on the pharmacological and chemotherapeutic properties of niridazole and other antischistosomal compounds was held by the New York Academy of Sciences from 10 to 13 October.

Professor BRIAN MAEGRAITH (Liverpool) opened the meeting by outlining the magnitude of the world problem of schistosomiasis, which is estimated to afflict 200 million people or roughly 1 in 10 of the world's population. Repeated courses of different schistosomicides are at present advocated for the cure of individuals in highly endemic zones, but Dr. A. H. MOUSA (Cairo) described trials aimed at mass chemoprophylaxis. In view of the possible theoretical development of resistance to any single drug and of toxicity due to them, he had employed combinations of subtherapeutic doses of antimonial and non-antimonial drugs in different schedules in infected mice. Despite variable results the combination was encouraging, particularly since there were different biochemical effects between antimonial and non-antimonial schistosomicides. Mice that had been infected with *Schistosoma mansoni* continued to excrete non-viable eggs for up to one year after treatment with niridazole (Ambilhar) even although there were no longer signs of active parasitism. Dr. C. R. LAMBERT (Basle) referred to them as black eggs or empty shells.

Niridazole is rapidly absorbed and accumulated in the vitellogenic gland of the female worm, and decrease in worm length and in the size of the worm ovary shows a clearcut dose-effect relationship. Dr. H. P. STRIEBEL (Basle) emphasized this sensitivity of the female and the relative refractoriness of male-worm testes to such treatment.

Orally administered radioactive niridazole is slowly absorbed from the gastrointestinal tract over several hours, and then rapidly broken down by a nitroreductase enzyme system in the liver. Dr. J. W. FAIGLE and Dr. H. KEBERLE (Basle) pointed out that this combination of slow absorption and rapid metabolism ensured a uniform concentration

of niridazole in the blood throughout the period of its absorption.

Professor A. W. WOODRUFF and his co-workers at the Hospital for Tropical Diseases (London) had compared the value of toxicity of sodium antimony tartrate, antimony dimercapto-succinate, sodium antimony gluconate, Anthiomaline (anthiolimine), lucanthone, and niridazole, bearing in mind the useful practical definition that a schistosomicide must be capable of eradicating heavy and light infections of all strains from persons of different racial, residential, and other characteristics when given in a regimen easy to apply under varying conditions. The main disadvantage of niridazole was the neuropsychiatric disturbance which particularly complicated its use in hepatosplenic bilharziasis.

Hepatosplenic Disease

Professor A. M. COUTINHO and Dr. A. M. DOMINGUES had carefully studied 52 patients in Brazil receiving niridazole for the hepatosplenic form of the disease. In 20 treatment had had to be stopped because of side-effects, which included psychoses, often with suicidal tendencies, in 19 and convulsions in four patients. Serial electroencephalograms had shown changes in 15 of 18 patients studied. In the intestinal form of the disease only two of 30 patients had developed any of these complications. To some extent these side-effects could be minimized by the administration of barbiturates and tranquillizing agents. Dr. A. ABDALLAH (Cairo) described episodic excitement, euphoria, and hallucinations from the fourth day of treatment onwards; and also mental disorientation, generalized convulsions, and localized muscle tremors and spasms. Though the overall incidence of toxicity was less than 1%, it had been found to rise to about 28% in adults with *S. mansoni* infection and the hepatosplenic form of the disease. This was unlikely to be due to hepatocellular poisoning, for

serum-transaminase levels and bromsulphalein excretion were essentially unimpaired during treatment. Dr. A. RUAS, studying similar patients in Mozambique, had noted that liver biopsies showed no histological change after niridazole therapy compared with pretreatment sections.

The cerebral sequelae may be related to portal-systemic venous shunting, which is a feature of hepatosplenic schistosomiasis. This would allow niridazole to reach the brain without being metabolized by the liver. Dr. J. W. FAIGLE and Dr. H. KEBERLE (Basle) demonstrated high peripheral blood levels of the drug in patients with hepatosplenic schistosomiasis. Professor SHEILA SHERLOCK (London) believed that the mechanism was analogous to portal-systemic encephalopathy, in which products of bacterial action on protein bypassed the liver and induced hepatic coma. Impairment of liver function would facilitate the effect; hence the increased frequency in the malnourished and in older patients rather than children.

Despite its toxicity in hepatosplenic disease, it was agreed that niridazole was the drug of choice in *S. haematobium* infections. Dr. V. CLARKE (Rhodesia) had found that such infections were easily cured by niridazole in a dosage of 25 mg./kg. body weight for five to ten days—an experience which proved universal. Dr. G. RAFFIER (Ivory Coast) felt that the excellent therapeutic and prophylactic results obtained in vesical bilharziasis allowed her to predict its eradication by a mass campaign comprising niridazole for the bilharzial patients, together with a molluscicide for destruction of the intermediate host, the snail.

Dr. F. FONTANILLES (Basle) summed up the situation succinctly by balancing the risks of treatment (including the effect on the myocardium of some schistosomicides) with the tolerability and efficacy of niridazole in mass campaigns—particularly of children suffering from *S. haematobium* infections, in which it was of unequalled efficacy and suitable for outpatient therapy.

Extracorporeal Filtration

Dr. B. H. KEAN and Dr. E. I. GOLDSMITH (New York City) described an ingenious method of recovering adult schistosomes, based on their peculiar localization in the portal circulation. The portal blood was diverted through a catheter inserted in the splenic vein and was returned to the circulation through a saphenous vein after being filtered extracorporeally. The worms were mobilized from the intestinal venules by the intravenous injection of antimony and were trapped in the filter as they passed towards the liver. Up to 2,000 worms might be recovered in a single procedure. So far, however, haemofiltration of the perivesical plexus for *S. haematobium* infection had been unsuccessful.

Dr. C. H. TAMBURRO and Dr. C. M. LEEVY (New Jersey) had extended the observations by assessing the immunological response of patients with active infestation who were being dewormed by means of extracorporeal filtration of their portal vascular beds following antischistosomal treatment. A serological schistosomiasis plasma card

test using a cercarial antigen emulsion had been found easy, highly specific, and effective in screening an endemic population in a non-endemic area for schistosome infestation. This semiquantitative method of measuring antibody titre was related to the degree and severity of infection. Antibodies, produced against cercarial antigen, were found to be 7S globulins of the IgG fraction; they were predominantly responsible for the hypergammaglobulinaemia seen in active infestation. A direct correlation was apparent between severity of infestation, height of cercarial antibody titre, and level of IgG in all 17 patients with tissue evidence of schistosome eggs.

Other Infections

Dr. S. J. POWELL (Durban) demonstrated that niridazole was highly effective in both bowel and liver infections. A trial of niridazole with dehydroemetine revealed that it was just as effective as chloroquine in liver abscess. Nevertheless, the efficacy of combi-

nations of well-established amoebicides and the advent of metronidazole was thought to leave little place for niridazole in the treatment of amoebiasis.

Dr. G. RAFFIER (Ivory Coast) and Professor O. LUCAS (Ibadan) emphasized the broad-spectrum, antihelminthic value of niridazole, which was highly effective in the treatment of strongyloidiasis and dracontiasis. The recommended dose was 25 mg./kg./day for one week, administered in divided doses twice daily. Absence of parasites in the stools and an improvement in health were rapidly achieved in most patients with strongyloidiasis, and likewise there was an elimination of the guinea-worm in almost all subjects infested with *Dracuncula medinensis*, with a corresponding rapid relief of pain, tenderness, and swelling. It was also noted that the worms were extracted more easily and there was less tendency for fresh worms to emerge. Niridazole was well tolerated, and minor side-effects were controlled by antihistamine drugs.

The transactions of the Congress will be published by the New York Academy of Sciences.

HOSPITAL TOPICS**Organization of Hospital Work in Scotland**

[FROM A SPECIAL CORRESPONDENT]

Clinical Organization

Under the auspices of the Scottish Home and Health Department a conference was held in B.M.A. Scottish House in Edinburgh on 2 November to consider the first report of a Joint Working Party on the "Organization of Medical Work in the Hospital Service in Scotland" (see *B.M.J.*, 4 November, p. 291). Among those attending the conference were representatives of the Central Department, regional boards, boards of management, and hospital medical staff.

The Working Party, which consisted of members nominated by the Department and the Joint Consultants Committee (Scotland), was appointed in December 1965 by the Secretary of State for Scotland with the following terms of reference: "To consider what developments in the hospital service are desirable in order to promote efficiency in the organization of medical work." The Chairman of the Working Party was Dr. J. H. F. BROTHERSTON (Chief Medical Officer of the Scottish Home and Health Department), and Dr. J. G. M. HAMILTON (Chairman of the Scottish Joint Consultants Committee) presided over the conference.

In his opening remarks Dr. HAMILTON pointed out that the detailed study of the remit had been undertaken by subgroups of the Working Party, but the report now presented represented the joint and agreed view of the Working Party as a whole. He emphasized that the conclusions were in no sense to be regarded as instructions to anyone; they were recommendations for discussion and consideration by all concerned—at national, regional, and hospital levels.

Introducing the chapter of the report dealing with clinical organization, Dr. BROTHERSTON said it seemed to be inevitable that medical development tended to outstrip organization. The present pattern of grouping in individual firms or units, each operating more or less independently, dated from older and simpler times, and was well suited to preserve continuous consultant responsibility in patient care. With the increasing complexity of specialist service, however, it was becoming evident that this system might not give the best results either for patients or for teaching. The problem was to organize without adversely affecting independent consultant responsibility. The Working Party believed that this could be achieved by the larger-scale organization in "divisions" which it recommends. The corresponding working party for England and Wales had independently reached the same conclusion.

Touching on the advantages of the proposed divisional system, Dr. Brotherston spoke of its greater flexibility in deployment of beds to meet the needs of developing specialties with much less disturbance than was now the case. Other variable needs—such as those arising from epidemics, seasonal changes in morbidity, intensity, and type of patient care needed—would all be more readily met. The system could provide an effective means of forming and transmitting collective opinion and advice on hospital policy and development. This would supplement, not replace, the role of medical staff

committees. So far as training was concerned, while the present organization provided the obvious advantages of apprenticeship, it was difficult under it to provide the variety needed for a complete training in the modern situation. This would be more easily achieved under the proposed plan. It would also be easier to develop methods of evaluating work done in hospitals.

The Working Party had adopted the term "patient-care evaluation" as more nearly expressing what was in mind than the American "medical audit." Speaking of the possibility of improved co-ordination with other specialties and services, Dr. Brotherston drew attention to the similarity of their own recommendations to many of those in the Salmon Report on nursing organization. In conclusion, he said the Working Party believed that clinicians would have to interest themselves actively in organization and administration if they were to play their full and necessary part in the "tactics and strategy" of the Health Service.

Consultant Responsibility

Sir JOHN BRUCE (S.E. Region and Joint Working Party) thought that some among the senior clinicians might regret the passing of the old order under which they had long worked happily, and suspect the change to be a sort of committee system. The proposals were, however, designed to preserve the principle of consultant responsibility and, he believed, would be welcomed by the younger

group. The "divisional" type of organization was not in fact new and had been in operation in some specialties in several areas for some time. This was also true of so-called medical auditing.

Dr. P. MACARTHUR (N.E. Region) doubted whether the divisional organization could be introduced voluntarily, and argued in favour of divisional chairmen being appointed by regional boards from among the senior clinicians, as proposed by the English working party. The appointment should be for five years. Mr. W. M. FARQUHARSON-LANG (N.E. Regional Board and chairman of the Departmental Committee on Hospital Administration) thought the proposed organization could lead to improvement in the medical advisory arrangements for hospital boards. It would be necessary to provide effective administrative support for the chairmen of divisions and for the committee of chairmen. In reply to Dr. W. P. U. KENNEDY (S.E. Regional Hospital Junior Staff Group) Dr. BROTHERSTON said the place of junior staff within the organization had not been forgotten in the deliberations, but would need more discussion "on the ground." Other matters raised by speakers included the financing of effective medical auditing and the role of medical superintendents under the scheme.

Dr. C. W. CLAYSON (Western Region and Joint Working Party), introducing Chapter II on medical staffing, said the Working Party had recognized at an early stage that the basis of any discussion on staffing problems must be the existence of a chronic shortage of doctors. In spite of an increase over the past dozen years of 30% in senior and nearly 60% in junior staff, there was still a serious shortage. The numbers in general practice meanwhile were actually falling. The factors creating this situation would continue to operate, and hence there was a need to relieve medical staff as much as possible of non-medical duties by providing them with technical and secretarial assistance, and for delegation by consultants of duties which could be undertaken by appropriate intermediate staff. The Working Party had concluded that one paramount need was to foster reintegration of hospital and general practice, which would be to the benefit of both.

Other sources of staff were part-time employment in hospital of local authority doctors engaged in specialist preventive work in the paediatric, geriatric, and mental health fields; married women doctors; and retired doctors. This would mean a substantial expansion of the medical assistant grade, with a compensatory reduction in the registrar establishment—which would be desirable in the interests of a better balance between staffing and training needs.

Dr. JOHN SMITH (Scottish Home and Health Department) felt that the association of general practitioners with the hospital was most important. A recent survey had shown that there were twice as many aspirants to a hospital career as there were likely vacancies, whereas only half the number needed for general practice wished to enter it. He felt sure that many in both groups would be well content with a career that combined the two. The combined local authority and hospital appointment would also be attractive to many.

Dr. A. ALLISON (Western Region) and two other speakers expressed concern about the proposed expansion of the medical assistant grade. This might lead to a recurrence of the old senior hospital medical officer problem. Dr. CLAYSON did not think this likely under the new organization, though there might be problems in connexion with delegated responsibility.

Use of Beds

Mr. A. H. JACOBS (Western Region and Joint Working Party), introducing Chapter III—Alternatives to Traditional Systems of Hospital Care—said the Working Party were concerned to know whether the present system of admission to and treatment in hospital provided both the best and most economic use of hospital beds. They had reached the conclusion that several changes could usefully be made—including planned admission to hospital (with separation of the emergency and waiting-list cases); development of selective patient grouping according to clinical need; and the allocation of beds to provide this flexibility. Several categories could be distinguished, such as routine acute care beds (including intensive nursing care beds); intensive therapy beds; and short-stay beds, perhaps divided into overnight and observation beds, and five-day beds.

Dr. MACKAY HART (Western Region and Joint Working Party) said building changes would be needed to put many of these ideas into effect, but quite a lot of them could be realized without this. Dr. ERIC SAMUEL (S.E. Region) thought there was room for better planning of radiological, laboratory, and other investigations of inpatients. Several speakers suggested, and Mr. JACOBS agreed, that a great deal more information would be needed before many of these changes could be approved and adopted.

Mr. N. G. C. HENDRY (N.E. Region and Joint Working Party), in introducing Chapter IV on Operational Research, discussed the techniques involved and their application to medical work generally and hospital work in particular. These covered such things as routine statistics, assessment of standards of care, and work study. The cynic, he said, might argue that people could spend so much time investigating the work they were doing that they ended up doing no work at all. The Working Party were convinced that great benefit could come from intelligent use of these methods, and they recommended further strengthening of the Health Department's Research and Intelligence Unit.

"Communications"

Mr. E. U. E. ELLIOTT-BINNS (Scottish Home and Health Department) spoke briefly to Chapter V on Communications, pointing out that the term "communications" was not altogether satisfactory, but it was difficult to find a more suitable one. It was concerned essentially with ways and means of getting information to those for whom it was necessary or useful. He drew the attention of the conference to two of the Working Party's proposals—namely, the establishment of some kind of "staff college," which would be concerned with the study of and training in

management, and the appointment of a small standing committee representative of the various interests to devise and keep under review the channels of communication within the service.

In closing the meeting Dr. HAMILTON said that the Department hoped very much that the report and its recommendations and proposals would be thoroughly and critically discussed by doctors and others all over the country.

NEW APPLIANCES

Prototype Cryosurgical Probe

Mr. P. MCKELVIE, Institute of Laryngology and Otology, London, and Mr. O. H. SHABEEN, Guy's Hospital, London, write: This prototype cryosurgical probe is 15 cm. long, the low temperature tip being 1.5 by 0.5 cm. Operating from a cylinder of carbon dioxide, it reaches minus 40° C. in one second and defrosts electrically in eight

seconds. It is autoclavable, light, and portable, and is particularly suitable for the destruction, with haemostasis, of small lesions accessible in the upper air and food passages, though its general applicability is widespread.

It is manufactured by Spembley Products Ltd. and distributed through Keeler Ltd., London.

Correspondence

Letters to the Editor should not exceed 500 words.

Postoperative Gas Gangrene

SIR,—Your leading article "Postoperative Gas Gangrene" (14 October, p. 68) is a timely reminder of the unexpected and, fortunately, unusual risk run by the patient after surgery. This risk exists despite exhaustive efforts to control the environmental and personal sources of *Clostridium welchii*. I believe clostridial cellulitis and myositis occur more commonly than is realized.

Since the opening of a small hyperbaric oxygen unit three years ago 16 cases of post-operative and post-traumatic gas gangrene have been admitted from a relatively small population. Answers from a group of orthopaedic surgeons indicated that more than 50 cases had occurred in a population of three million in five years. You state that gas gangrene is a rare and terrifying disease, as indeed many diseases have been prior to methods of control.

Gas gangrene, however, has yielded over the last 10 years to a most effective form of treatment, hyperbaric oxygen, first reported by Boerema.¹ Van Zyl,² reporting on 200 cases treated all over the world, revealed a mortality rate of 2.9% when excluding those moribund on admission and dying within 24 hours. At our unit³ we have had patients in extremis with toxicity and confusion recover within hours, and had only one death in 16 patients with established gas gangrene. The cause of death was liver and renal failure.

The improvement is caused by transporting oxygen in plasma to the ischaemic tissues and preventing the elaboration of toxins by *Cl. welchii*. It is the ischaemia and anoxia which prevent penicillin destroying the organisms in the wound, and these proceed to produce toxins which cause tissue necrosis and even death.

Hyperbaric oxygen treatment renders the patient fitter for surgery and limits the procedure to excision of sloughs, with avoidance of dramatic amputations. There are facilities for hyperbaric oxygen treatment in many centres in the United Kingdom, and it is surprising that you did not refer to this therapy in your welcome article. Indeed, it is in the United Kingdom that so much of the impetus and development of the hyperbaric oxygen facilities has occurred. It is to be hoped that, while the evaluation of this therapy in other fields proceeds, the opportunity is not lost for rendering this life-saving method to the victims of surgery and trauma.—I am, etc.,

ROY H. MAUDSLEY.

Abortion Act

SIR,—While most doctors are in favour of greater latitude under the law, many may now be wondering whether the latest legislation on abortion, like that on road traffic, has taken sufficient account of the increased burden it places upon the overworked general practitioner. It was fairly obvious that there were not enough gynaecologists for the law to demand their involvement; but is there really any good reason to suppose that general practitioners are in a better position to take over even the whole consultative element from the present criminal practitioners?

The introduction of social grounds is going to call for a great deal of fact-finding and assessment which, to say the least, will require an enormous amount of liaison with the social and welfare services. For instance, the emotionally disturbed expectant mother who already has an overcrowded home will not only present a need for general-practitioner psychotherapy and a certificate to the housing authority but the possibility of abortion will have to be considered. Ethically, this might be regarded as the last resort, but patients and housing committees may well tend to favour it for its relative simplicity. Once precedents are established in any one family or district it will become increasingly

difficult for any doctor to stand out against abortion becoming accepted as the remedy for many of the social evils that have long been crying out for fundamental solution.

The present law, for all its harshness and injustice, has enabled the doctors to take up a position with regard to abortion that is sufficiently simple and well-defined to render administration by them relatively easy. The new law will inevitably far more often depend on the interpretation and judgement of general practitioners, with a much greater need for thorough investigation of the grounds. These, as we have seen, will range over a very wide field. Thus as time goes on there will develop another considerable factor to be taken into account by members of the public in making their choice of doctor from a competitive profession. This would become increasingly significant if Governments ever decided to reverse the policy of giving more and more work to fewer and fewer medical practitioners. In this context one may wonder what remuneration there will be for the abortion service and how it will compare with that relating to the Mental Health Act.

Although one would not wish to quarrel with the House of Commons' decision that two medical practitioners should be responsible for

administering the new law to patients, it may be felt that in practice considerations such as those to which I have alluded make a wider and more impersonal system desirable. In relation to the Mental Health Act the nomination of local standing referees has worked very well, and possibly something like this idea could grow up as an unofficial institution suited to the Abortion Act and the needs of some areas. Incidentally it is possible that we may even evolve the surgeon-abortionist to replace his criminal counterpart and take the load off the shoulders of gynaecologists whose operation and waiting lists will probably remain full enough without any additional work.

Undoubtedly there is a lot to be said for leaving room for natural evolution of the detailed administrative machinery for coping with all the problems that can be foreseen. However, there can be no objection to the consideration of possible ways of dealing with the whole situation during the six months before we are actually called upon to cope with it. I would like to propose for consideration the appointment of "local abortion committees." There would be permanent membership recruited from obstetric committees and public health authorities or other sources of medical, legal, and social expertise. Whether cases for abortion should be submitted compulsorily or voluntarily, or whether the patient, her doctor, or local health visitor or any other witnesses of fact or opinion should attend meetings, are matters to be decided in general or in any particular case. Obvious advantages of such a system are the relatively consistent and impersonal decisions and precedents that would arise out of it. It would also tend to be more efficient and less onerous than the separate and varying personal efforts of different pairs of general practitioners. This especially because judicial and sociological ability will be comparatively more important than medical science.—I am, etc.,

Eye,
Suffolk.

J. SHACKLETON BAILEY.

Hiatus Hernia and Coronary Disease

SIR,—Dr. M. Atkinson's masterly account of hiatus hernia (28 October, p. 218) requires some comment. As he states in his final paragraph, hiatus hernia is extremely common in elderly patients with coronary disease, so that we often encounter chest pain from the combined lesions. Anginal pain may be conditioned by a number of coincident extra-cardiac diseases—for example, gall-bladder disease, cervical spondylosis, and notably by hiatus hernia, especially the para-oesophageal type, in which cardiac pain may occur mainly or even exclusively at night or after meals.

I have now seen so many patients with serious coronary insufficiency dragged from their beds to be radiographed in an inverted posture and at much peril that some warning is needed. Patients with this combined lesion may die in their anginal attacks. One of my patients reached the stage when he refused to eat and passed the night on a chair. When he died suddenly his wife was so sure that

the trouble arose from the stomach that she demanded a postmortem, which showed advanced coronary disease with old occlusion and a hiatus hernia, the size of a tangerine.

Dr. Atkinson states that hiatus hernia may cause pain down both arms, though he qualifies this by remarking that such pain is usually cardiac. In my experience it is always cardiac. Certainly before such symptoms are attributed to hiatus hernia careful electrocardiographic investigation is required, and, whenever possible, a record during the pain should be obtained. This can sometimes be accomplished by laying the patient flat or by a mild exercise test immediately after a good lunch.

Dr. Atkinson mentions the diagnostic difficulty in such cases and warns us that the consequences of error may be serious. I am sure that he will forgive me for emphasizing this particular point.—I am, etc.,

London W.1,

D. EVAN BEDFORD.

Surgery in Pulmonary Tuberculosis

SIR,—I am concerned that your leading article on surgery in pulmonary tuberculosis (21 October, p. 127) might be misunderstood. I imagine that some of the implications which might be drawn from it were not in fact intended by the writer, but I feel I should draw attention to them in case other people also misconstrued his intentions. The first indication for surgery mentioned is the most surprising: "those patients with cavitated disease who after six months of adequate chemotherapy are still producing positive bacillary tests, particularly where the original organism showed an appreciable degree of resistance to the standard antituberculous drugs." Many physicians would now agree that if proper treatment is given to a newly diagnosed case (streptomycin, P.A.S., and isoniazid, in appropriate rhythm and dosage) the sputum of all patients who do not die within the first week or two should convert to negative. Cultures were negative in about 98% of my own series at six months, but the remaining 2% converted by 10 months. Genuine failure will occur only if the patient has initial drug resistance to more than one of the three drugs used or he has not taken his treatment. In the former case this should be known by three months after starting treatment, and appropriate alteration of chemotherapy should ensure later sputum conversion. Cavitated tuberculosis should be treated under sufficient supervision to ensure that the patient takes his drugs. Surgery may perhaps be justified in some patients with localized disease known to have organisms resistant to all the standard and some of the reserve drugs, and perhaps this is what the author really had in mind.

In suggesting some of the other indications for surgery the writer does not make clear the necessity for ensuring that active tuberculosis has been eliminated. Such patients will require at least 18 months of effective chemotherapy to ensure them against relapse, no matter when operation has been carried out or what its nature.

We have done so little surgery for tuberculosis over the last 10 years that it is difficult to comment on the suggestions regarding thoracoplasty, which have the nostalgic flavour of past controversy. Nor is it easy

to comment on the suggestions regarding the resection of intrathoracic lymph-glands in primary tuberculosis, which I have, perhaps incorrectly, never regretted not having done. On the other hand, I am happy to be able to agree that there is a definite place for surgery in infection with atypical mycobacteria, which are at present so much less controllable with chemotherapy.

I feel that this article, I am sure unintentionally, has been slightly haunted by ghosts out of the past. I hope I will be forgiven for a little gentle exorcism.—I am, etc.,

JOHN CROFTON.

Department of Respiratory
Diseases,
University of Edinburgh.

SIR,—In your leading article "Surgery in Pulmonary Tuberculosis" (21 October, p. 127) you mention the treatment of enlarged tuberculous mediastinal glands in children by repeated bronchoscopic aspiration or alternatively by thoracotomy and excision or evacuation of these glands. Lest medical staff working in areas where primary tuberculous infection with enlarged mediastinal glands is still seen should conclude that surgical treatment is the best method, I should like to draw your attention to a study conducted at this hospital on 383 child patients. The results of this study were presented at the annual conference of the British Tuberculosis Association at Oxford in 1965.¹

All children admitted to the hospital suffering from primary pulmonary tuberculosis with consolidation-collapse from 1952 to 1959 were carefully followed up for periods ranging from 6 to 13 years. Bronchoscopy was done in only 12 patients, and in these two showed normal appearances, five oedema of the mucous membrane, one a block by granulation tissue, one a block by external gland pressure, two showed strictures, and one a stricture with sinus formation. Thoracotomy was not resorted to early in treatment but only if after a period of expectant treatment the consolidation-collapse failed to clear. In fact only 21 children (5.2%) required thoracotomy—ten had a lobectomy, seven a segment resection, one a lobectomy with removal of glands, two a segmental resection with removal of glands, and one removal of glands only. The end results of treatment were satisfactory in 338 patients who were traced; 41 were lost sight of. Two children who had recovered well died after discharge—one from appendicitis and one from a road accident, and two died early in the course of treatment from tuberculous meningitis.

This study has not yet been reported in full, as a further follow-up is being carried out in a group of children who showed marked clearing of calcium deposition from the affected segments of lung and/or from calcified mediastinal glands. Quite large masses of calcification have been found to disappear gradually from the lungs over periods of three to ten years, a phenomenon not thought to be so common previously. Sweany² has described peculiar phagocytic cells in the lung which arise from basic reticulum cells in the lung or from monocytic cells which come in from the blood stream. He showed that they have the capacity to reabsorb calcium deposits from the lung tissue. I mention this because, although one is aware of the severe lesions which occur in primary tuberculosis with consolidation-collapse, and of the excellent work done in this connexion by Seal *et al.*,³ nevertheless our

long-term results of conservative treatment lead to the conclusion that surgery should not be undertaken under one year from diagnosis; in fact, Harley Stevens⁴ suggested 18 months. A graph of the time at which x-ray clearing of the consolidation-collapse appeared in our series showed peaks at two to three months and seven to nine months. Treatment by bronchoscopic aspiration is of limited value, a finding also borne out by Bentley and Grzybowski.⁵

The human body appears to have remarkable powers of healing if given time, and in young children the experience of repeated bronchoscopy, which can be hazardous, or of major chest surgery are probably best avoided.—I am, etc.,

JOHN B. MORRISON.

Body Building on Drugs

SIR,—I have recently been approached by a person who is interested in body building and weight lifting and who has asked me if I would consider giving him anabolic steroids. He alleges that a very large percentage indeed of the top flight of both body-builders and weight-lifters take these drugs, and he feels that he would have gone further if he had taken them. He also says that there is a ready availability of these drugs on the "black market." I feel under some moral pressure in this case, as he will abide by my decision whether I give them or not, but not winning competitions will entail undoubted financial loss in his line of business.

My object in writing to you, Sir, is four-fold. (1) To bring more into the open a newer aspect of drug-taking. (2) To inquire whether your readers feel it is justified to prescribe this class of drug for body building, bearing in mind the side-effects—quite apart from the ethical aspect. (3) To ask whether the governing bodies of these sports feel a stand should be taken against such artificial methods of "training." (4) To inquire whether the easy detection of persons being given steroids is feasible at competitions and games.—I am, etc.,

Westcliff-on-Sea,

Epidemic Keratoconjunctivitis

SIR,—After an interval of eleven years epidemic keratoconjunctivitis has returned to the Clyde Valley conurbation (for report see page 366). The causal agent, adenovirus type 8, is very hardy. Though poorly infectious by casual personal contact in European or North American conditions, this virus is highly contagious and transmitted easily by the fingers, instruments, and medicaments of the ophthalmologist or in the industrial ambulance room. Infections of medical,

paramedical, and nursing staff have been observed in the present outbreak, as in the past. Scrupulous attention to hygiene and sterile techniques is necessary to stop the spread of this infection, which can cause painful disability for many weeks with residual corneal opacities. Since fingers seem particularly likely to transfer infection, it would be advisable to use disposable gloves for manipulating eyelids when rushed conditions prevent thorough cleansing of hands between patients.—I am, etc.,

Department of Infectious
Diseases,
Glasgow University.

N. R. GRIST.

Obstetric Forceps or Vacuum Extractor

SIR,—Your leading article (23 September, p. 753), inspired by the excellent paper of Schenken and Serr,¹ makes certain dogmatic pronouncements over and above their findings. Such is the influence of the *B.M.J.* that these should be questioned forthwith before they become accepted as orthodox doctrine on this topic.

You state that forceps are to be preferred for the management of delay or foetal distress in the second stage because "delivery will be quicker." Certainly it will, but application of forceps requires either a formal pudendal nerve block or a general anaesthetic, both of which take some minutes to organize. The hazards of the latter you ignore. It is debatable whether the combination of minimal anaesthesia and vacuum extraction is in fact much slower than a properly anaesthetized forceps delivery.

"Delivery is safer because a doctor cannot hope to apply the forceps correctly and effectively until he has checked the position of the occiput." To be certain of the position of the occiput a general anaesthetic may be required, and this carries its own risks. Manual rotation and forceps extraction are definitely easier to perform under general anaesthesia. This is in marked contrast with deliberate application of the cup to the occiput when the latter is posterior, using local infiltration anaesthesia, or at most a pudendal block. In the majority of cases the unique ability of the vacuum extractor to promote flexion of the foetal head is then followed by autorotation and a comparatively rapid occipito-anterior delivery. The minute force often necessary to produce this manoeuvre makes it one of the most aesthetically satisfactory obstetric procedures.

"Damage to the scalp by necrosis at the site of the application of the vacuum cup is not uncommon." Nearly all writers in fact agree that it is extremely rare unless traction is continued for longer than 40 minutes.

You conclude, "The vacuum extractor has no place on the district or in a general-practitioner maternity unit." This appears to be in direct opposition to Schenker and Serr's conclusions: "its principal advantages . . . are the lack of necessity for general anaesthesia . . ." (surely of great value in such units) and "the correction of pathological vertex positions such as persistent occipitoposterior and deep transverse arrest" (most general-practitioner obstetricians would agree that these cause them more anxiety than the rest of operative obstetrics put together). They further conclude that,

"with respect to the mother, the vacuum extractor is a relatively safe instrument as compared to the forceps." "The danger of ascending infection appears to be minimal (5 to 6%) as compared to 15.3% in forceps deliveries. . . ."

The enormous value of the vacuum extractor in one general-practitioner unit has been previously described.² Subsequent experience of a further 40 cases has confirmed this view. Naturally the instrument has its limitations, but the fact that it has largely replaced the forceps in several countries on the Continent, whose results compare favourably with our own, must speak for itself.—I am, etc.,

Prevention of Rh-haemolytic Disease

SIR,—We read with interest Professor C. A. Clarke's article (7 October, p. 7) and the leading article (same issue, p. 3) on prevention of Rh-haemolytic disease. In this hospital we have been using 1-ml. doses of Rh human immunoglobulin ("RhoGam," Ortho, U.S.A.) for the past 18 months in a trial to prevent Rhesus sensitization in women at risk.¹ To date we have injected 45 patients. The following case is of interest, particularly in the light of Professor Clarke's article.

The patient's first pregnancy ended in an abortion at 12 weeks in February 1965. Evacuation of the uterus was required, but no transfusion. Her blood group is A Rh-negative, genotype cde/cde (rr) and no antibodies were present; and that of her husband A Rh-positive, CDe/CDe (R₁ R₂).

In her second pregnancy (expected date of delivery 22 April 1966) she received an intramuscular injection of antirubella gammaglobulin at the 11th week. The pregnancy proceeded normally, no versions were performed, and no antibodies were present at the 32nd week. She had an easy forceps delivery at 41 weeks' maturity, there being no difficulty in the third stage. Cord blood showed direct Coombs test negative, and the baby's group was A Rh-positive (D); maternal blood sample two hours post delivery showed a foetal cell count per 50 low-power fields of 15, and no antibodies were detected. In view of the leak of foetal cells she therefore received an intramuscular injection of 1 ml. RhoGam 32 hours after delivery; there was no reaction, local or general. Foetal cell counts after injection showed that the cells had been completely cleared within 24 hours, and remained clear; antibody test at six weeks showed a titre of two; and four-months and six-months post-injection tests showed no antibodies.

Between her second and third pregnancies she had six normal periods until the last one on 21 December 1966. She received no injections of any description, and there was no question of a miscarriage.

In her third pregnancy (expected date of delivery 28 September 1967) no antibodies were detected at the 22nd or 32nd weeks of pregnancy; external cephalic version was performed on three occasions, at the 37th, 39th, and 40th weeks. She had a normal delivery at term of a living child after a labour lasting five and a half hours. The direct Coombs test on the cord blood was strongly positive; the baby's group A Rh-positive (D); the serum bilirubin 1.75 mg./100 ml., and the haemoglobin 14.89 g./100 ml. The maternal blood taken two hours after delivery showed no foetal cells; anti-C + D

antibodies were present—complete antibodies to a titre of 16, incomplete to a titre of 256.

It may be of significance that the immunized case in the Liverpool trial, and in ours, both had antirubella globulin during the previous pregnancy. We feel confident that the immunoglobulin we use, which has an anti-D titre of 20,000 to 80,000 by Coombs technique, cleared the foetal erythrocytes from the maternal blood, as four counts subsequent to its injection failed to reveal any circulating cells. Whether the globulin prevented sensitization at that time is open to question, though no evidence of antibody formation appeared in the interval between the second and third pregnancy.

Another point of interest is whether the rapid rise of antibodies after the 32nd week was related to the three external versions performed, which could have caused significant transplacental foetal bleeds.

The success figures Professor Clarke quotes from the various centres are so impressive that it seems important to investigate every failed case in detail in order to discover the cause.—We are, etc.,

Acute Industrial Poisoning

SIR,—The use of poisonous gases in warfare has been rightly condemned, but it seems that we may not be so fortunate to avoid being gassed in peacetime. Recently property not far from a hop-processing plant in Kent was inundated by clouds of sulphur dioxide gas emanating from the plant. The immediate result was the defoliation of apple-trees, burning of grass, and withering of rose and fruit bushes. Those people who were in the way of the gas experienced distress in breathing. After-effects are difficult to assess.

In my own case a minor viral infection a week or so later turned into an acute bronchitis requiring several weeks' sick leave and treatment with antibiotics. It appears the growers are well aware of the destructive nature of this gas, as they make sure their own crop is fully gathered before liberating the sulphur dioxide. It would be interesting to know if any of your correspondents have experienced this form of acute industrial poisoning. Clear Air Acts aim to protect city populations from chronic poisoning due in some measure to sulphur dioxide. It would seem that some legislation is needed to protect the public against an acute hazard of this sort.—I am, etc.,

East Farleigh,

DENIS APIVOR.

Vasectomy for Contraception

SIR,—In view of the increasing public interest in vasectomy more surgeons are being approached to perform this operation. As a surgeon who has been working in a male infertility clinic for 20 years I would like to point out some of the pitfalls.

Counsel's opinion for the Medical Defence Union states that the operation is illegal if done only for the purpose of birth control.¹ To cover the surgeon legally it is essential to have a second opinion from a general practitioner, a psychiatrist, or a gynaecologist to the effect that further pregnancies are likely to endanger the mental or physical health of a man's wife.

The surgeon should discuss the operation of bilateral vasectomy, and its implications, with both partners, and obtain the written consent of both husband and wife to the operation.

At operation it is wise to excise 1 cm. from each vas deferens, and both open ends should be ligated with linen thread or silk, rather than catgut. If the excised portions are sent for microscopic examination there can be no doubt that the vas deferens has been tied. Congenital abnormalities of the vas deferens are more common than one thinks.² One per cent. of all men attending an infertility clinic have bilateral absence of the vas deferens; a smaller number have absence of one vas. I have found one case of duplication of the vasa, and probably more will be found as vasectomy becomes more common.

After bilateral ligation of the vas deferens semen analysis must be carried out at monthly intervals for some months to make sure that the seminal reservoir is completely empty of spermatozoa. The patient must be told that contraceptive measures are required until he has had at least one azoospermic ejaculate. If spermatozoa in fair numbers persist for more than three months the possibility of faulty technique, or duplication of the vasa, must be considered and an exploratory operation performed.—I am, etc.,

Institutional Care of the Mentally Subnormal

SIR,—Professor T. McKeown and Dr. Ian Leck have recently reminded us (2 September, p. 573) that numbers of patients in hospitals for the mentally subnormal are not in need of hospital care. Attempts are being made in many areas to transfer such patients to the care of local authorities, and local authorities are increasingly providing hostels to meet this need. Transfers from hospital to local authority hostels are typically arranged by having local authority representatives interview selected patients, both to assess their suitability as hostel residents and to enable an estimate to be made of the number of hostel places that the local authority need provide.

At the present moment, for a variety of reasons (delays in building programmes, etc.), a considerable proportion of patients accepted for local authority hostels tend still to be on waiting-lists three or more years after their initial interview. Delays such as this are not something with which the mentally subnormal can happily cope, and from interviews I have conducted with 34 such patients on a waiting-list for one local

authority hostel it is clear that they are on the whole very disappointed people indeed. Instead of interviewing patients and accepting them for "hostel X to open in four years' time," can we not postpone the interviews until hostel places are actually available? It may be argued by local authorities that patients must be interviewed in advance in order to plan the number of hostel places needed, but statistics for planning purposes can in fact be obtained by other means (vide McKeown and Leck). It is hoped that the present situation, whereby numbers of patients are suffering disappointments through transfers to local authority hostels not being speedily effected, will not be allowed to persist.—I am, etc.,

ALISON C. CAMPBELL.

Department of Social and
Preventive Medicine,
University of Manchester.

SIR,—I would like to comment on your leading article "Place of the Mentally Retarded" (2 September, p. 567) and the article by Professor T. McKeown and Dr. I. Leck (same issue, p. 573), but lack of space restricts me to a few remarks only.

Ever since the inception of mental health departments of local authorities increasing numbers of mentally handicapped children have been brought to the authorities' attention with subsequent requests for their disposal. From the practical aspect, therefore, more placements will have to be found for them in the near future, both in the community and in hospitals. You quote that large numbers of institutionalized mental defectives could be placed in open employment. The implication that any chronic institutionalized patient could be easily integrated into community life is somewhat contrary to past experiences. It applies even more so to the severely mentally subnormal patient who constitutes a large proportion of chronic institutionalized patients of most hospitals for mental subnormality. As a considerable number of them suffer from an additional physical disability, an even greater obstacle to open employment is thereby created. This was discussed elsewhere.¹

If we consider the high-grade subnormal patients, especially those without physical handicaps, then their place should certainly be in the community. But let it be stated here there is an understandable reluctance on the part of hospitals to discharge their brighter patients, the ones for whom community facilities were essentially designed, because these patients fulfil a most useful function in the daily running of the hospitals with their present-day acute staff shortages. Professor McKeown and Dr. Leck suggest that responsibility for training should be transferred from the local health authority to the education authority and a group of resident patients transferred to the local health authority. As for educationally subnormal (E.S.N.) pupils these are already under the care of the education department, although some children needing psychiatric advice are sometimes reluctantly and belatedly sent to child guidance clinics.

When, however, we consider the "ineducable" pupil (an objectionable term) we are confronted with quite a different problem. He represents the lower grades of mental subnormality, and the present system of junior training schools and attached special care units under the

aegis of the mental health departments provides the most suitable environment for such a handicapped child. I would therefore make a plea for the retention of mentally subnormal in junior training schools under medical direction, but suggest closer collaboration with the education department for readier consultation and referral from one professional discipline to the other. What about those children who reach the arbitrary school-leaving age for handicapped pupils at 16 years? If junior training centres were administered by education departments do Professor McKeown and Dr. Leck suggest that the same departments should continue to care for those post-school adolescents when they enter adult training centres—quite a novel function for an education authority—or should mental health departments then take over with the introduction of yet another new set of welfare officers?

One other point requires mentioning. The staff of child guidance centres should be brought together under one department, not Education, as at present, where all services for the adolescent cease when he reaches the age of 16, but Health, which could thus form a more closely knit unit in conjunction with the local mental health department. This team then would continue to counsel and guide the teenage patient during those formative and impressionable years until he qualifies for treatment and supervision by an adult department. It should be noted that facilities for the older teenager are almost non-existent at present and by the time he has reached the age of 16 he is "either too old for the child guidance clinics or too young for adult departments of hospitals," and thus receives little or no counselling or guidance.

The suggestion made in your leading article which may cause difficulties in practice refers to the mixing of patients with various types of mental disabilities in one centre. The behaviour and temperament of subnormal people is often totally different from that of trainees suffering from other mental afflictions. Further, one trusts that the remark about the transfer of resident patients to local authority establishments will not be construed to mean the wholesale transplantation of inmates of chronic hospital wards into the community. It should be reiterated that the mentally subnormal, with or without physical defects, who require nursing attention or medical care cannot be contained in any community hostel, and owing to the chronicity of their mental state require hospitalization for the remainder of their lives.—I am, etc.,

Hypercalcaemia and Malignant Tumours

SIR,—Although he found it "longish," Mr. W. M. Keynes (23 September, p. 799) might not have found the discussion on the mechanism of the hypercalcaemia in malignant tumours "less interesting" than the rest of our paper (2 September, p. 590) if he had read it with attention. His statement that "hyperplastic parathyroid glands have not been found in such patients" is contradicted by our quotation of the work of Massaro and Owen,¹ and of Krane and Roth,² who found chief-cell hyperplasia. We quoted an additional point in favour of a mechanism mediated via the parathyroids³ in that removal of these glands has caused lowering of the serum calcium.

Mr. Keynes is right that some tumours produce a parathyroid hormone-like substance,

as shown by direct evidence quoted by him and by ourselves, but this does not remove the possibility that in the other cases the effect is produced via the parathyroids. His parade of facts such as the prompt fall in the serum calcium after surgery, the absence of skeletal metastases, and the hypophosphataemia, all of which could equally well occur with either mechanism, and his reference to Albright's suggestion in 1941⁴ that tumours of non-parathyroid origin might produce a substance with the activity of this hormone avail nothing. The latter prognostication merely indicates how far advanced in his thought this individual was, and in fact no such hormone was found in that case by the methods then used. Furthermore, in so far as it is not totally irrelevant owing to the different hormone system involved, Mr. Keynes's reference to the work of Liddle *et al.*,⁵ who found corticotrophin, or a closely related polypeptide, in tumour tissue, supports the possibility of an indirect hormonal effect.

As we stated, direct evidence alone in each case will be the final answer. We would be genuinely grateful if Mr. Keynes, if he forgives us our sharpish reply, or anyone else, could assay the tumour in our case for hormonal activity, as we still have half of it in the deep-freeze. The patient remains entirely well three years after operation.—We are, etc.,

Swallowed Dental Reamer

SIR,—It is common practice to adopt a conservative regimen in the management of swallowed sharp foreign bodies, surgical removal being indicated if the object does not pass or if signs of penetration occur. This report of an unusual dental accident illustrates the value of early accurate radiological diagnosis as an indication for emergency surgery.

A 28-year-old ex-dental nurse was having a root filling performed when the dentist dropped the reamer into her mouth (Fig. 1). She realized the dangers of swallowing and attempted not to do so. However, the reamer could not be found and the patient was therefore sent to the local hospital, where x-rays of the chest and abdomen were interpreted as showing no foreign body. Two hours after

FIG. 1.—Magnified view of dental reamer. Actual length 3.1 cm. Diameter of haft 0.5 cm. Though superficially resembling a Malay Kris, it is a fine spiral drill.

returning home the patient began to experience ill-defined colicky epigastric pain and sought a second opinion. Physical examination indicated no abnormality apart from minimal epigastric tenderness. A plain abdominal x-ray film showed the shadow of the reamer in the right abdomen (Fig. 2). There was no free intraperitoneal gas. Although the reamer lay in a position corresponding to the vertical part of the duodenal loop, the lateral projection showed it too far anteriorly to be in the duodenum. Therefore the patient was given a mouthful of barium. Further films showed the reamer fixed in the pyloric antrum, the wall of which it had penetrated (Fig. 3). Emergency laparotomy revealed it firmly embedded in the wall of the antrum, which was impregnated with

FIG. 2.—Supine abdominal film showing reamer lying vertically to the right of the spine. Is it in the duodenum?

FIG. 3.—Barium meal film (rotated view) showing reamer having penetrated wall of antrum. Indication for immediate operation.

dental amalgam. The reamer and adjacent wall were removed, and the patient made an uninterrupted recovery, leaving hospital on the fifth postoperative day.

This experience demonstrates that barium contrast examination is a safe, speedy, and accurate method not only in assessing location but also penetration of the bowel wall by a sharp pointed object.—We are, etc.,

Dyspepsia

SIR,—Dr. N. F. Coghill's paper on dyspepsia (14 October, p. 97) condenses a great deal of clinical wisdom into a small space. The presence of one or more of the following symptoms or signs could also be helpful in pointing to a demonstrable organic cause in the differential diagnosis between "organic dyspepsia" and that which remains of uncertain cause after investigation:

- (1) Abdominal pain sufficiently severe to wake the patient up.
- (2) Localized abdominal pigmentation from frequent use of a hot-water bottle.
- (3) Waterbrash (defined as a sudden outpouring of saliva).—I am, etc.,

H. J. GOLDSMITH.

Paraproteins and Bence Jones Protein

SIR,—Dr. E. N. Wardle (7 October, p. 56) is quite right in that the Bence Jones protein excreted in the urine does not absolutely represent its total daily production, but to what extent in man is unknown. In the very recent paper he quoted¹ it was clearly shown that only some 20% of a 1–2 μ C intravenous dose of ¹³¹I-labelled Bence Jones protein appeared in the urine of mice. Much of the remaining 80% appeared to have been catabolized by the kidneys of the mice. However, the amount of protein involved is not stated; it may have been only a milligram or so, and no effect of dose-load was investigated.

In the other paper he quoted² it is also clear that, with apparently normal renal function, two patients excreted only 10% of their slight Bence Jones production, up to 3 g./day being catabolized. With the enforced retention and high blood levels following on renal failure three other patients catabolized up to 50 g./day, presumably throughout the body tissues. However, with Bence Jones proteinuria of 1–20 g./day in the absence of renal failure (as in most of our patients) I can find no data to show how much Bence Jones protein is catabolized, or how important is the role of the human kidney. Certainly among very many patients with renal diseases due to causes other than myelomatosis I have detected no gross excess of light chain excretion (above 10 mg./day). Therapy with γ G-globulin did not result in any significant increase in light chain excretion,³ and Putnam's⁴ original work showed that Bence Jones proteinuria reflected largely the *de novo* synthesis of Bence Jones protein, not a catabolic breakdown product of whole myeloma immunoglobulin.

Thus Bence Jones proteinuria does indicate abnormal synthesis. In the M.R.C. Myeloma Trial survival of patients producing only Bence Jones protein is already significantly worse than in those with comparable Bence Jones proteinuria but also with a parent myeloma protein. Thus the latter patients produce more paraprotein daily, run the same risk of renal failure, but, presumably because their myeloma cells can still make some whole immunoglobulin, they do not appear to be as malignant as the former. This is the as yet unpublished evidence for the statement that the shift to only "the production of

Bence Jones protein indicates further differentiation" (misprinted as "differentiation" under Fig. 2).¹ Irrespective of the proportion catabolized, Bence Jones proteinuria seems to carry a worse prognosis. I hope this has clarified the issue.—I am, etc.,

Glucagon and Intravenous Glucose Tolerance

SIR,—Mr. D. A. Turner and his colleagues (21 October, p. 145) claim that "it is unlikely that glucagon-induced elevation of plasma insulin levels is responsible for the superiority of oral over intravenous glucose tolerance." They may be right, but their own data are inconclusive. Thus the two individuals in their series who received the low-dose glucagon infusions (0.6 µg./min.) showed only small increases in blood sugar levels compared with the control infusion, yet showed definite differences in plasma insulin levels. Had the authors tried an even lower rate of glucagon infusion, it is at least conceivable that the insulinotropic effect might have remained, while the glycogenolytic effect was lost. It is conceivable because that is the trend suggested by the authors' own figures.—I am, etc.,

Intestinal Spirochaetosis

SIR,—In reference to the letter by Dr. S. C. Dyke (21 October, p. 176) we wish to point out that Dr. A. G. Shera described a form of granular proctitis, which he termed "the strawberry lesion" and which he claimed was due to Vincent's organisms originating in an oral or pharyngeal infection. He also found that many of the patients had vitamin-C deficiency. A fully illustrated account is found in the *British Journal of Surgery*.¹

The connexion between this condition and the one we recently described (16 September, p. 718) remains to be established. The organism we described averages only 3 µ in length and appears as a pure growth on the epithelial surface, while the spirochaete Dr. Shera found in swabs of the rectal lesions averaged 11 µ in length and was invariably associated with fusiform bacilli. This perhaps indicates that these conditions are not identical.—We are, etc.,

Dysmenorrhoea

SIR,—Your leading article (21 October, p. 125) repeats several fallacies which I had hoped were long interred. The "psychogenic" theory of dysmenorrhoea may be convenient for the doctor, but it is hardly comforting to the unfortunate victim of crippling uterine colic to be told that "it's all up here" when she knows "it's all down there." And therapeutically the theory is of little or no value. I had also thought that the "hypoplasia of the uterus" and "stenosis of the cervix" theories were nowadays totally abandoned. Neither has any anatomical or pathological basis. It is similarly disappointing to see aspirin and a "healthy psychological outlook" (whatever that may mean) and "attention to exercise" still prescribed. Nothing depresses a patient more than such predictably ineffective treatment.

The basis of the pain, as you somewhat reluctantly agree, is hypercontraction of the uterus, postulated by Muir 30 years ago, and the coincident ischaemia still remains the most satisfactory explanation. The cause of the myometrial hypersensitivity is less precise, but it is almost certainly connected with inflammatory and degenerative changes found in the tracts and ganglia of presacral nerves removed from these patients.¹ This is supported by the beneficial effects of sympathectomy, which acts not only by severing the sensory pathways but also by cutting off contractile efferents. Dydrogesterone acts similarly by partially paralysing the myometrium. A great many patients are relieved by the contraceptive pill, and this must remain the initial treatment of choice. For those unable to tolerate hormone therapy dilatation of the cervix is generally advocated. But this procedure is effective only when the endocervical sympathetic plexus is ruptured, and this is attained only by using the higher grades of bougies—a process which you rightly associate with possible future incompetence. In any case, it helps only a quarter of the patients. Much superior is alcohol-injection of the pelvic plexus.² This is simple and safe with proper technique, and gives a cure rate of 70%.—I am, etc.,

Railroading in Retinal Vessels

SIR,—Dr. P. J. Tomlin's interesting comments on this phenomenon (16 September, p. 722) deal with cases of restored circulation after cardiac arrest.

It may be worth pointing out that it is incorrect to assume, as is commonly done, that "railroading" necessarily signifies a

state of cardiac arrest. I recall, when a houseman in neurosurgery, being informed during the night that an adolescent girl had died. She had been in deep coma with an incurable intracranial lesion, and was on continuous positive pressure respiration. On examining her, heart sounds were inaudible. The fundi showed the characteristic fragmentation of blood in the vessels, which is often said to be a sign of death and *ipso facto* of cardiac arrest. However, the fragments were moving along in one direction in a faintly pulsatile fashion, and cardiac arrest was clearly not present. Later, during the same night, I was again notified of the patient's apparent death, but it was eerie to find as before that the movement of the blood fragments showed persistence of a sluggish circulation with a regular though faint pulsation. It was only during the following morning that death was deemed to have finally occurred.—I am, etc.,

M.A.O. Inhibitor Headache

SIR,—Dr. C. A. H. Watts has reported (28 October, p. 238) two cases where blood-pressure readings were found to be near-normal soon after onset of severe headache associated with monoamine oxidase inhibiting drugs. His observations provide interesting confirmation of an earlier report¹ suggesting that the blood pressure is not always raised in patients taking monoamine oxidase inhibiting drugs who develop such headaches.

It may not be generally known that the majority of these headaches, which can be not only devastatingly severe but also protracted over some days, can be swiftly relieved by the slow intravenous injection of 5 mg. phenolamine (Rogitine). Furthermore, it is interesting that this measure appears to be as effective in the normotensive¹ as in the hypertensive setting.²—I am, etc.,

Early Discharge of Maternity Patients

SIR,—Early discharge of maternity cases is now an established procedure in many areas (26 August, pp. 517 and 520); the advantages and disadvantages are well known, and there is no need to recount these. Above all, in areas where there is a shortage of beds it is a means of offering the safety of confinement in hospital to a large number of women. Mothers at high risk are more willing to enter hospital knowing they can return home early, and the problem of the home which is inadequate for confinement but adequate for nursing is solved. What was an emergency arrangement has proved so popular with patients that there is no doubt it has come to stay. However, for the smooth running of such a scheme good planning is necessary, and these plans will depend on the structure of the community to be served.

Thorpe Coombe Maternity Hospital is in Walthamstow in the outer London area. It has a total of 70 beds for antenatal care, first stage of labour, and the lying-in period. Since planned early discharge was introduced four years ago confinements have increased to over 2,000 annually. The hospital serves three local authorities, and for the success of the scheme close co-operation is essential. Patients for early discharge are selected during the antenatal period by a consultant. The request may come from the mother herself or her family doctor, or the hospital may ask if she is able to be nursed at home after 48 hours. Selected mothers sign an agreement and provide the hospital with the name and telephone number of their doctor and district midwife. In all cases the home is visited and assessed by a district midwife, thus ensuring her co-operation, and the general practitioner and local authority are notified. These plans having been made well in advance, discharge from hospital can proceed as a smooth routine. The antenatal care of the patient is shared by the hospital, general practitioner, and district midwife, so that she is known to all concerned.

Before discharge all mothers and infants are seen by the obstetric registrar, and in case of doubt are referred to a consultant obstetrician or paediatrician. If necessary they are detained in hospital for longer than 48 hours. Each morning the ward sister notifies a clerk of the patients for early discharge and she then informs the family doctor and midwife. The patient, who has been up and about, leaves by private transport accompanied by a relative. This has proved a satisfactory arrangement and an ambulance is seldom required. Very few patients have needed readmission to hospital. In one of the areas concerned these mothers are cared for by a retired midwife working part-time, in the other two areas by the full-time midwives. In addition to mothers booked for early discharge those booked for home confinement who are admitted in late pregnancy or labour are allowed home early provided they are fit.

The arrangements described were arrived at by trial and error accompanied by good will. They are simple and require no elaborate administrative machinery. They provide additional safety for many mothers and infants, and this makes the additional work worth while.—I am, etc.,

D. JOAN BRYSON.

Thorpe Coombe Maternity Hospital,
Walthamstow, London E.17.

Fallacies in Four Fevers

SIR,—I support the suggestions for shortening the official period of infectivity of childish fevers (7 October, p. 41). But might it not be better to go even further?

School epidemics are poorly controlled by exclusion of children with infectious fevers. It is much less inconvenient, and often less unpleasant as well, to suffer these illnesses when young. Therefore I believe it would be better to abandon ineffective attempts at control, and instead try to infect as many children as possible. In order to do this I propose that *general policy* be one of inclusion, rather than of exclusion, of well but infectious children with rubella, mumps, and chicken-pox. Infectious measles children are not in any case well enough for school.

This policy would only be general, and schools could at any time declare a season of exclusion during important exam terms and the like. Families with special reasons for not wanting an infectious member would keep their children from school, but should in logic exclude also all uninfected members from public places during the epidemic.—I am, etc.,

Bury St. Edmunds,
Suffolk.

JOHN E. HODGKIN.

SIR,—Professor R. S. Illingworth's short article (7 October, p. 41) was as usual full of common sense, and I am in complete agreement with his conclusions. With regard to school exclusion of cases and contacts of the common infectious diseases, the following recommendations were adopted in Oxford in February 1963:

Disease	Minimum Period of Exclusion from School provided child appears well	
	Patients	Family Contacts
Chicken-pox	Seven days from appearance of rash; all the scabs need not have separated.	There is no routine exclusion of contacts of any of these infectious diseases but individual children may be excluded on the advice of a general medical practitioner or a school medical officer.
Dysentery (Sonae)	Until complete cessation of diarrhoea.	
Measles	Seven days from appearance of rash.	
Mumps	Until disappearance of all swelling.	
Rubella	Five days from appearance of rash.	
Scarlet Fever	Until clinical recovery.	
Whooping-cough	Until clinical recovery.	

There has been no subsequent occasion on which there has been cause to regret departing from the more rigid criteria laid down in the Ministry of Education Memorandum 1956, which is of course advisory rather than mandatory.—I am, etc.,

Oxford.

JOHN F. WARIN,
Medical Officer of Health,
City of Oxford.

Treatment of Poisoning by Anti-depressant Drugs

SIR,—Dr. A. B. Masters (30 September, p. 866) and Dr. C. A. Fuge (14 October, p. 108) both draw attention to sudden relapse and death after seeming recovery from the effects of an overdose of a tricyclic drug. In their original paper (9 September, p. 663) Dr. C. M. Steel and his colleagues also noted this unusual outcome.

It is of great practical and theoretical interest to know the cause of these sudden relapses. They may perhaps be directly caused by persistence of the drug or one of its metabolites, but it is also possible that they result rather from some special feature of the drug-induced illness, and only indirectly from the drug itself. Thus Dr. Steel and his colleagues warn against the risk of precipitating circulatory collapse by allowing patients to be physically active as soon as they seem to have recovered from the overdose. The drug leaves a cardiovascular sensitivity behind it, and physical strain might cause relapse.

I wish to draw attention to the possibility of permanent brain damage which may arise

where there is a long delay in instituting treatment. Status epilepticus, hypotension, and hyperpyrexia damaged the brain in the following case:

A normal boy weighing 12.7 kg. and aged 14 months was able to crawl and use five distinct words. He opened a screw-cap bottle and took four to eight tablets of desipramine hydrochloride (Pertofran, Geigy, 100-200 mg.). His parents put him to bed, where next morning he was found to be unrousable. When he reached hospital, 15 hours after his overdose, he was in status epilepticus, with clonic convulsions every five minutes, a weak irregular pulse (40/min. at apex), blood pressure unrecordable, and a rectal temperature of 41° C. Electrocardiogram showed a chaotic mixture of ventricular and supraventricular tachycardia with wide QRS complexes.

Intravenous thiopentone and 100 mg. hydrocortisone were given. Fourteen hours after admission fits had ceased, the blood pressure was 80/50 mm. Hg, pulse was 190 at the apex, and the E.C.G. showed regular ventricular tachycardia. Procaine amide, 50 mg. intravenously over five minutes, produced a slower but irregular ventricular rhythm. Next morning, however, systolic blood pressure was 100 mm., pulse 120 regular, and E.C.G. showed sinus rhythm, but the patient remained unrousable. Two days later convulsions returned, and 15 were noted in the next 13 hours in spite of renewed thiopentone. They ceased when 14 g. urea was given intravenously over half an hour (as 30% "Urevert") to reduce cerebral oedema.

Thereafter the child made only a partial recovery. After 19 days an E.E.G., kindly performed by Mr. D. Lee (Warneford Hospital), showed a medium voltage arrhythmic slow wave pattern in all leads without evidence of any cortical activity. When seen five months later he lay sucking his thumb, rhythmically emitting a constant feeble whine if it was pulled out of his mouth. He could take his weight on his legs, but could not maintain his balance for standing or sitting. His pupils reacted to light, but there was no comprehension of visual stimuli. He opened his mouth to receive food when a spoon touched his lips. Hunger and discomfort caused wailing. Pain made him turn from supine to prone in evasion.

The special feature of this case was the long delay in instituting treatment, as in Dr. Masters's case.

I am grateful to Dr. Desmond MacCarthy for permission to publish this case.

—I am, etc.,

Woodstock,
Oxford.

W. R. EDWARDS.

Acute Necrotizing Encephalitis

SIR,—In your leading article (30 September, p. 812) referring to a recent report by two of us¹ on eight cases of acute necrotizing encephalitis you state that, "If an exploratory biopsy is carried out, however, necrotic brain only will be found. . . ." This might seem to imply that cerebral biopsy is of no value in establishing the diagnosis of acute necrotizing encephalitis, when in fact the reverse is the case. In four of the five original cases, and in two more recently encountered, examination of a cerebral biopsy disclosed the characteristic histological features of acute necrotizing encephalitis.

You also observe that it is still uncertain if acute necrotizing encephalitis is due to direct virus invasion or represents yet another antigen-antibody reaction, and whether herpes virus is the only cause or the only one so far demonstrated. We have now encountered 10

cases in which the clinical and pathological features were typical of acute necrotizing encephalitis. From five of these brain biopsy material was examined by virus isolation studies and four yielded herpes simplex virus; three of these have been previously reported.² In all seven cases from which suitable tissue was available for electronmicroscopic study virus particles belonging to the herpes group have been identified.³ This seems convincing evidence that most cases of acute necrotizing encephalitis are due to direct invasion of the brain by herpes simplex virus.

The possibility of the successful treatment of acute necrotizing encephalitis with idoxuridine⁴ makes it vital to establish the diagnosis of herpes simplex encephalitis as early as possible in the disease before neuronal necrosis is advanced. As the results of virus isolation, the testing of paired sera for complement-fixing antibodies, and electronmicroscopic examination are unlikely to be available for several days, histological examination of brain biopsy material is likely to remain the most important means of making an early diagnosis. Fluorescent antibody studies for herpes simplex virus may also be of considerable value in making a rapid preliminary diagnosis, but their reliability in herpes encephalitis has not yet been adequately assessed.—We are, etc.,

Diet and Diverticulitis

SIR.—One is well aware of the important contribution to the understanding of diverticulosis coli by Mr. N. S. Painter (12 August, p. 434), and his studies on the pressures generated by segmentation.¹ However, the constant fact remains that both sigmoid volvulus and diverticulosis occur in Ethiopians on the same diet and under the same conditions, although admittedly the former is much more commonly recognized. It is incorrect to state that these "African natives living on a tribal diet do not develop diverticulosis."²

Dr. B. Yovanovich in a busy hospital practice reports an unchanged radiological incidence of approximately 30 cases annually of diverticular disease in Ethiopians.³ These barium enema studies show great variation in the length and diameter of the colon, and there must be many other factors than the simple theory advanced by Drs. Cleave and Campbell of the effects of refined and unrefined carbohydrate eating habits.—I am, etc.,

Courtesy between Colleagues

SIR.—A few years ago¹ I wrote to you complaining about the Institute of Directors' Medical Centre examining patients of mine without my reference. This produced some interest from *The Times*,² and also from other doctors who were kind enough to write to me supporting my complaint.

Soon afterwards I met the director of the institute, and he promised to do his best to get in touch with the general practitioner before examining his patients. I regret that this has not yet happened with my patients, and I have been concerned to find that they

still receive a carbon copy of the verbose report sent to me. Recently I spent a rather difficult time going through such a report, paragraph by paragraph, with the patient concerned, and doing my best to explain it and reassure him.

Is the long-established tradition of courtesy and contact between medical men passing?—I am, etc.,

P. B. SCHOFIELD.

Walton-on-Thames,
Surrey.

Prospects for Hospital Doctors

SIR.—While the Health Departments are to be congratulated for attempting to give some guidance on prospects by publishing the official figures for 1965 and 1966 (*Supplement*, 24 December 1966, p. 240, and 7 October 1967, p. 3), the profession should not be blinded by their star-studded appearance or fail to compare these sets of figures with those found in HM.64(94) [a Ministry of Health circular in 1964 on hospital medical staffing structure]. Such an exercise is thoroughly depressing.

In terms of whole-time equivalents (W.T.E.) boards in England and Wales considered an additional 1,806 consultant posts ought to be created by September 1968. This figure of 1,806 was scaled down to the so-called median figure of 1,095, which incidentally had the effect of reducing the target for additional posts in general medicine from 194 to 113, in general surgery from 150 to 64, in pathology from 201 to 109, in psychiatry from 281 to 205, and in obstetrics and gynaecology from 109 to 48—to mention a few of the larger specialties. From the time the boards made their returns in 1964 to September 1966 406 W.T.E. new consultant posts had been created and for the three-year period September 1963 to September 1966 this gave a figure of 603.9 W.T.E. new posts. This left the need to create a further 689 new posts by September 1968 if even the scaled-down figure of 1,095 (406+689) was to be reached.

It is to be noted that in the Ministry's recent tables the column showing expected consultant vacancies is based on the sum of the average annual expansion rate over the last three years plus the expected existing posts which might fall vacant (if it is a good year for the actuary). The average consultant expansion over the three-year period 1963–6 was 202. Projected to September 1968 this should add 404 posts (if the present rate is maintained)—285 short of the already scaled-down target and 996 short of the target the boards themselves thought should be aimed at in the original reviews.

Recently I investigated what plans hospital boards had made for expansion in psychiatry over the next three years. Senior administrative medical officers were extremely helpful, but the results of this survey painted a very different picture from that suggested by the Ministry's charts and in no way reached the expansion figures these anticipate. In summary, if boards were to have reached the original review target by September 1968 they would have needed to have plans for an additional 201 posts (100 per annum for each

of the two years 1966–7, 1967–8); to reach the scaled-down median target plans for 140 (70 per annum); and for the Ministry's latest target plans for 33 per annum. In fact they had plans, albeit tentative in many cases, for an average of 13 new posts per annum over the next three years. And this despite the fact that there are some 200 senior registrars in training. Appalling though this is in a specialty where consultants are trying to practise modern psychiatry with ridiculously heavy case loads—the number of inpatients alone can be as many as 200–400 (600 is not unknown)—an equally important point is what would be revealed if similar investigations were made at board level of the expansion they have in mind for other specialties?

Meanwhile the service suffers and the work load on existing consultants increases, encroaching more and more on time that could be devoted to postgraduate teaching and research. Senior registrars—nearly 700 of whom are over 35 years and 161 over 40 years—to say nothing of the many excellent registrars with appropriate qualifications and training, become more disenchanted and emigrate.

In such a situation to increase further the number of junior staff of either registrar or medical-assistant type is no answer. The former merely intensifies the bottleneck problem. The latter grade, while it may prove to be the answer for getting general practitioners and others back into the hospital, is unsuitable for highly trained specialists waiting in the queue for consultancy. Indeed, the very creation of assistant posts could have the much more sinister effect of suppressing the proper expansion of the consultant grade, with the inevitable result of consultant work being performed by junior grades and all the understandable resentment that produces.

Since I am assured that the Central Advisory Committee on Consultant Establishments never turns down a needed consultant post, the conclusion must be that either hospitals are not asking for them or boards are failing to forward requests that are made.

The machinery is obviously going wrong somewhere. The time must have come for each specialty to lay down objective criteria on which hospitals could base their need for consultants. If this is not done and implemented soon an increasing number of potential consultants will continue to emigrate.—I am, etc.,

EDMUND A. HARVEY-SMITH,
Chairman,
Hospital Junior Staffs Group,
British Medical Association.

Kingston,
Surrey.

Casualty Staffing

SIR,—On examining the recently published figures (*Supplement*, 7 October, p. 3) for medical staffing in the National Health Service at registrar and S.H.O. levels one should under "traumatic and orthopaedic surgery" really read "casualty." If the departments which are major employers of these grades are compared the following figures are obtained. The total numbers are given in brackets, followed by the percentage of graduates born in the British Isles (as estimated from the Tables).

Specialty	Registrars	S.H.O.'s
Pathology	(231) 62%	(143) 56%
Anaesthetics	(506) 60%	(343) 53%
Psychiatry	(433) 59%	(153) 47%
General medicine	(615) 63%	(456) 46%
Paediatrics	(158) 47%	(205) 45%
General surgery	(676) 48%	(657) 37%
Obstetrics and gynaecology	(369) 42%	(449) 37%
Ophthalmology	(126) 49%	(92) 24%
Traumatic and orthopaedic	(314) 34%	(377) 19%
Otolaryngology	(131) 33%	(101) 19%

In the specialties of anaesthetics, pathology, and psychiatry it is probable that most, especially of the home-produced graduates, will eventually stay in these specialties, and the numbers in general medicine, general surgery, and obstetrics and gynaecology are helped by preregistration regulations. In casualty only a small proportion can hope to be recruited to consultant rank and the only inducement to take a casualty post at present is the requirement for F.R.C.S.

The casualty departments are mainly staffed by overseas graduates, and as the medically underdeveloped countries expand their postgraduate training this supply will diminish. While being grateful for their services, there are too many casualty departments being staffed by those without previous hospital experience in this country or sufficient training for such responsibility. The present system is also unfair on the overseas graduates. More than six months in a casualty department as S.H.O. grade is a waste of time, but it is my impression that too many are drifting rather aimlessly from casualty post to casualty post simply because they are relatively easy to obtain.

In some quarters it has been suggested that casualty departments should be staffed by consultants or medical assistants. To cover 24-hour duties and holidays this would mean a minimum of four for every casualty department. Even if the medical manpower situation were less critical I am certain that candidates in sufficient numbers would not be forthcoming. It would also be very expensive. The separation of accidents from other casualties would not solve the problem. It would mean two sets of 24-hour services in place of one. Someone must do the triage.

While agreeing there is a need for more consultant supervision in many casualty departments, I am sure that the solution lies with those who are in or destined for general practice. To be an effective casualty officer the general practitioner must be free of his practice commitments when in casualty. This would mean an average of one to two weeks whole-time casualty duty or its equivalent for all general practitioners every year. Because

of the differences in distribution between general practitioners and casualty departments this might mean working several miles from home. I believe that six months in a casualty department does allow younger doctors to see many of the types of emergencies that he is going to meet in general practice and at the same time have more experienced advice at hand. If such appointments were to be a prerequisite for entry into general practice it would help general practitioners' training and solve the staffing problem of casualty departments.

It would be interesting to hear the views of general practitioners, since I am very sure that before long the Ministry will be forced, out of sheer necessity, to place this bone of contention on their plates.—I am, etc.,

London W.1.

GUY RIGBY-JONES.

Approval of Emergency Treatment Service

SIR,—I cannot let Dr. M. Mundy's letter (4 November, p. 299) pass without commenting on some of his assertions concerning the B.M.A. Emergency Treatment Service.

It was decided to make use of the Telephone Answering Service a condition of joining the deputizing part of the service, because experience has shown that receipt of messages from patients by the control centre second-hand, or even third-hand, frequently through the doctor's receptionist or caretaker, can lead to misunderstanding and delay in visiting the patient. Direct telephone contact between the person requesting medical attention and the nurse at the control centre leads in our view to a quicker service for the patient. In those provincial centres where the service is operating subscribers are quite satisfied with this arrangement, and the chances of confusion over the relay of messages are minimized.

Our experience is also that doctors welcome the opportunity of the combined facilities, as it enables them to enjoy their time off without the need to provide cover for the telephone. While undoubtedly problems over the mechanical transfer of calls do occur, these are not common enough to be a serious danger to the efficiency of the service. The suggestion that the Telephone Answering Service provides an economic cushion against losses incurred in running the deputizing service is totally false. In fact the Answering Service is provided at less than an economic cost.

It was considered to be inappropriate for the Association to sponsor a service which would enable doctors to contract out of all their evening and week-end responsibilities, and with this in mind the Central Advisory Committee originally recommended a maximum of 25 calls per month—a level which it was considered would have made it impracticable for doctors to transfer to the service all their out-of-hours work. For those doctors who wish to contract out of evening and week-end duties the new general-practitioner contract provides the necessary mechanism.

In the event, experience in the centres already operating shows that 12 calls per month is the average demand by doctors. Furthermore, it has been drawn to the attention of the Central Advisory Committee that

there are a number of doctors, particularly in London, who wish to transfer only a limited number of calls, or alternatively whose level of evening or night calls is rather lower than average and for whom the 25-call contract would be unnecessarily expensive. A revised contract which should be acceptable to these doctors has been drawn up.

As to the recommendation by Dr. Mundy that "The organizers must adopt a much more realistic attitude towards a viable Emergency Treatment Service" I can only answer that we have a large number of satisfied subscribers in the seven centres where the service is operating. Surely I need comment no further.—I am, etc.,

London W.C.1.

IVOR M. JONES.

Consultants' Views of General Practitioners

SIR,—I have been in general practice in the East End of London since 1921. Prior to 1948 I had eminent specialists out for consultation. To mention a few: Dawson of Penn, Horace Evans, Tommy Horder, Victor Bonney, Louis Carnac Rivett, and Russell Brain. These men always observed strict protocol and always paid complimentary remarks re my treatment both to patients and relatives.

In my experience the consultants I have met since 1948 are men of the same calibre, in dealing with the general practitioner, as the illustrious names I have mentioned. It would be a very sad day for the profession should any acrimony develop between consultants and general practitioners (16 September, p. 735).—I am, etc.,

WILLIAM BELTON.

London E.17.

Menace of Smoking

SIR,—There is not much reason behind the intemperate attacks in the *B.M.J.* (23 September, p. 753, and 14 October, p. 113) and in the press on the smoking of tobacco generally.

I raise a voice on behalf of the many millions of men who have enjoyed smoking moderately (as I have done for the last 50 years) and who have met death, or must encounter death, from causes other than can be placed squarely against smoking.

What appears to have been lost sight of are these points. Quick-dried cigarette tobacco is probably the killer and this possibly has been marketed only in the last two decades. There has been a clear distinction between pipe tobacco and cigarette tobacco, but this is now overlooked. Cigarette-smoking was a very, very common indulgence at the time of the 1914–18 war, and one might still name the type of cigarette rubbish that was the troops' ration. The utmost anxiety, the poorest food, the cheapest cigarettes, and a shilling a day was their lot. If ever there should have been a spate of lung cancer it should have been in the third decade of the twentieth century.—I am, etc.,

Hexham.

RICHARD BELL.

Vocational Training for General Practice

SIR,—Dr. Frank Gray chides me gently (21 October, p. 177) for my comment in the G.M.S. Committee debate on 7 September (*Supplement*, 23 September, p. 135) that conditions should be created in general practice in which young graduates could continue to practise medicine in the way they have been trained. The debate was about vocational training for general practice and the subject was the report produced by a subcommittee of which I was the chairman. My observations were made in my reply to points raised during the debate.

The situation must be viewed with the 1967 recommendations of the General Medical Council as to basic medical education in mind.¹ These say that basic medical education should give "the student knowledge of the sciences upon which medicine depends and an understanding of the scientific method." They also set a single objective for all doctors up to the time of full registration and define the object of basic medical education as being "to provide doctors with all that is appropriate to the understanding of medicine as an evolving science and art." . . .

In the pre- and post-registration hospital appointments graduates have at their disposal all the resources needed to investigate and treat patients and they are unlikely to seek careers in a branch of medicine where similar resources are not available. There is thus an immediate danger to recruitment to general practice unless it is clearly seen to offer the conditions that graduates want. Of course changes in the administration and organizational aspects of general practice are just as essential as simple access to departments of medical science in order to allow full expression of the art of medicine by doctors.

Dr. Gray speaks from a lifetime of experience in practice, but I believe there is no great separation between his viewpoint and my own, both of which are concerned to advance general practice as a branch of medicine well able to offer a challenge to a due proportion of able graduates now and in the future.—I am, etc.,

London W.8.

DONALD C. BOWIE.

Mileage Allowances

SIR,—The letters from Drs. D. L. Bennett and R. J. Purnell (21 October, p. 177) are an oversimplification of a very complex situation, and the interim mileage allowance which has been negotiated by the B.M.A., although far from acceptable to the members of the Committee concerned, should not lead to the suggestion made by Dr. Bennett that, "the junior medical staff have no faith in the B.M.A., and . . . large numbers of senior medical staff see no reason for returning to the fold."

Horsepower, in relation to the internal combustion engine, was originally computed upon a basis related to the bore of the engine cylinder, but variations in the stroke of the piston, leading to considerable differences in the volume, necessitated a reappraisal of the formula. At one time it was considered that 100 c.c. was equivalent to one horsepower, but in recent years the tendency has developed

for engines to be "over-square"—that is, with a bore exceeding the stroke. The efficiency of the engine is of course dependent upon many factors, but a modern engine of 1159 c.c. at 5,200 r.p.m. can develop, for example, 47 brake horsepower, but owing to the relatively large bore the rating on the old basis would be as high as 15 horsepower. I stress this point because it must be appreciated that any attempt to devise a mileage allowance based upon horsepower, an outmoded term, rather than cubic capacity measured in c.c., is quite impracticable as a basis for future negotiations.

The difficulty of adhering to the horsepower formula was recognized by local authorities employing doctors in the public health service at least as long ago as 13 July 1956 in Medical and Dental Council circular No. 29, when it was decreed that in the case of cars registered on or after 1 January 1947 10 h.p. would henceforth be equated with 1199 c.c. for the purpose of calculating mileage allowances. The General Whitley Council, which considers mileage allowances for all hospital employees, adopted the 10 h.p./1199 c.c. equivalent basis system in General Whitley Council circular No. 70 dated 3 January 1966 (applicable from 1 November 1965), but at that time the Staff Side of Medical and (Hospital) Dental Committee B refused to accept the increase of only ½d. a mile which was offered, since this was considered to be totally inadequate. This figure of ½d. a mile has now been replaced, on an interim basis only and without prejudice to continuing negotiation, by a figure of ¾d. a mile. It should be appreciated that, since negotiations must be carried out through the General Whitley Council, which has already accepted the figure of 1199 c.c. as equivalent to the outdated concept of 10 h.p., all future computations must be assessed upon a cubic capacity rather than a horsepower basis.

Although some hospital medical and dental staff may have been fortunate enough to have had their mileage allowances calculated upon the old concept that 10 h.p. is equivalent to 1000 c.c. instead of the 1199 c.c. defined by the General Whitley Council, it is surely unreasonable to indict the B.M.A. on this account. Realizing that in some instances an apparently unfair situation might arise, care was taken to write in a "no detriment" clause in the official circular N/C154/17B, which was issued by the Ministry in July 1967 to the secretaries of all regional hospital boards; boards of governors; hospital management committees; clerks of executive councils; joint pricing committees, and the dental estimates boards to the effect that: "where an officer . . . whose car in use at 30 June 1967 was over 10 h.p. but not over 1199 c.c., continues to use that car, he may retain the old rates until he changes his car. . . ."

The new rates of mileage allowances, which are effective from 1 July 1967 and will be published in G.C. circular No. 76, compare with the old rates as follows:

Old Rates		New Rates	
Cars up to 10 h.p.		Cars up to 1199 c.c.	
First 2,000 miles	7½d. per mile	8½d. per mile	
2,001–7,000 miles	6d. " "	6½d. " "	
Over 7,000 miles	4½d. " "	5d. " "	
Cars over 10 h.p.		Cars over 1199 c.c.	
First 2,000 miles	9½d. per mile	10d. per mile	
2,001–7,000 miles	7½d. " "	8½d. " "	
Over 7,000 miles	6½d. " "	6½d. " "	

While it is appreciated that the owner of, for example, a Morris 1100 will not for the present time be any better off, he will certainly not, owing to the "no detriment" clause, suffer

any reduction as Dr. Bennett suggests. The recently introduced 1250 c.c. engine for this model will of course place such a new vehicle in the higher mileage rate group.

The B.M.A. went to great lengths and considerable expense to prepare, through the Economist Intelligence Unit, assisted by representatives of the Automobile Association and Royal Automobile Club, a very comprehensive memorandum dealing with current motoring costs, which was not, however, acceptable to the Management Side of Committee B, and it is not always fully appreciated that it is extremely difficult to persuade the General Whitley Council that hospital medical and dental staff should receive preferential rates and conditions as compared with other hospital staff. Despite this, an interim increase of ¾d. a mile instead of ½d. a mile has been achieved; there is a "no detriment" clause to protect staff with cars previously rated on the 10 h.p./1000 c.c. basis; and further negotiations are being pursued to the maximum extent possible.—I am, etc.,

N. L. ROWE,

Member, Negotiating Subcommittee of Central Committee for Hospital Medical Services.
Woking, Berks.

Points from Letters

Lithotomy Position for Forceps

Dr. R. M. PEBERDY (Droitwich Spa, Worcs) writes: In the two years that I spent as senior house officer anaesthetist I and my colleagues in our anaesthetic team dealt with rather more than the average number of these cases, as one consultant obstetrician preferred general anaesthesia for his forceps deliveries. . . . It was always the rule that the patient should be anaesthetized with the legs down, and that intubation with a cuffed tube should always be performed. Only when the anaesthetist was satisfied that the trachea was protected by the cuffed tube and pack were the legs raised to the lithotomy position, which undoubtedly seemed the most convenient position for forceps delivery and other obstetrical manoeuvres. Also an efficient, working, frequently tested sucker was always provided wherever an anaesthetic was given (a portable sucker formed an essential part of the flying squad anaesthetic equipment). By means of these precautions, which took very little extra time or effort, the incidence of regurgitation was, I believe, reduced and if it did occur was comparatively easily dealt with.

Drugs and Schizophrenia

Dr. J. A. McCLUSKIE (Sydney, Australia) writes: I wonder if it was a coincidence that your leading article "Antibodies in Schizophrenics" (2 September, p. 569) was followed on the next page (p. 570) by your article on "S.T.P." It would be a peculiar turn of coincidence if underworld research into new hallucinogenic drugs did produce one which could be identified in the tissues of schizophrenics.

"Mediflash"

Dr. R. W. COCKSHUT (London N.W.4) writes: The famous flashing green-light application form states: "(2) only to be used in emergencies; . . . (6) if improperly used light will be withdrawn." What interesting implications there are here. It appears that the B.M.A. approves of a doctor being followed and questioned, and of the patient being questioned, so that someone (it could only be the police) could be satisfied that the call was a true emergency. A report then made to the B.M.A. would result in the green light being confiscated, never to be used again.

Obituary Notices

L. E. C. NORBURY, O.B.E., M.B., B.S., F.R.C.S.

Mr. L. E. C. Norbury, consulting surgeon to the Royal Free Hospital, to St. Mark's Hospital, West Middlesex Hospital, and Belgrave Hospital for Children, died on 31 October at his home after a short illness. He was 85.

Lionel Edward Close Norbury was born at the Cape of Good Hope on 9 January 1882. His father was a Barts man, Sir Henry

Norbury, K.C.B., Director General of Naval Medical Services. Lionel was educated at Merchant Taylors' School, and St. Thomas's Hospital Medical School, where he had a distinguished career as a student, taking the Cheselden medal, the Beane scholarship, and other prizes. He

qualified with the Conjoint diploma in 1904 at the age of 22, and graduated M.B., B.S. the following year. He passed the F.R.C.S. examination in 1906 at the age of 24 in the distinguished company of Lord Webb-Johnson and Sir Gordon Gordon-Taylor, but he had to wait until the following year, when he was 25, to receive the Diploma of Fellowship. He held resident surgical appointments at St. Thomas's Hospital, and in 1911 was appointed assistant surgeon to the Mildmay Mission Hospital, London. He served as captain in the R.A.M.C. throughout the first world war, and was appointed O.B.E. After demobilization he rapidly established himself as a sound general surgeon, and was elected surgeon to the Royal Free, St. Mark's, and West Middlesex Hospitals, and to the Belgrave Hospital for Children.

His merits were appreciated by the Royal College of Surgeons, where he became an examiner in surgery, a member of Council, and vice-president. He was Bradshaw lecturer in 1948, and Hunterian orator at the Royal College of Surgeons in 1953. He took an active part in medical societies, and was president of the Medical Society of London, and also orator to the Hunterian Society in 1955.

His general training gave Lionel Norbury an all-round interest in surgery, and although he had a special interest in proctology his surgical field was very broad. He had no special interest in research, but applied himself completely to the relief of individual patients. He took a personal responsibility for every case, public or private, and devoted himself wholeheartedly to the patient from the beginning to the end of treatment. He was scrupulous in all that he did, and no detail was too much trouble. He would carry out the first dressings of his major operations himself on all cases in hospital. He was always available, and on his duty

week in hospital he would always come and operate himself on emergencies, right up to the time of his retirement from hospital practice. Norbury was popular with his students, and his teaching was always clear, simple, and practical. He took a keen interest in examinations, and when he was on the Court of Examiners he never missed a single examination in his twelve-year period of office. He was a kindly examiner, and, although he demanded a high standard, his friendly disposition always helped to get the best out of his candidates.

Lionel Norbury was an outstanding example of the cultured professional gentleman. He had a splendid, impressive figure, tall and handsome, and he was always of a cheerful, friendly disposition. He was very happy in his private life. At the height of his career,

before the second world war, his home in Harley Street was a centre of social as well as professional activity, where his devoted wife, Grace, and their four charming daughters were the focus for many happy gatherings of youth and culture. At week-ends Norbury kept open house at Cowden, entertaining many of their friends with swimming and tennis parties, while he himself always took an active part and was never too tired for another set of tennis.

Lionel Norbury will be remembered by many doctors and patients with gratitude for his kindness and humanity. He had about him the rich glow of Christianity. His death will be mourned by many friends, but while they will be saddened by the loss of a great and good man they will be grateful to have had the privilege of having had his friendship. We extend our deep sympathy to his wife and to his daughters.—G. Q.

R. HALE-WHITE, M.C., M.A., M.D., M.R.C.P.

Dr. R. Hale-White, president of the Fellowship for Freedom in Medicine, a prominent figure in the profession and a practitioner of uncommon kindness and understanding, died on 31 October at the age of 72.

Reginald Hale-White, son of the late Sir William Hale-White, was born on 12 June 1895, and received his early education at Uppingham. During the first world war he

(Lawson)

joined the King's Own Yorkshire Light Infantry. He was severely wounded in the Battle of the Somme, and was invalided out of the Army. For his distinguished services he was awarded the Military Cross. Entering King's College, Cambridge, he graduated B.A., and took the M.A. in 1920. His father having been physician to

Guy's Hospital, and his uncle, Sir Alfred Fripp, having been surgeon, it was only natural that he should undertake his clinical studies at Guy's. Here, after qualifying with the Conjoint diploma in 1922, and graduating B.Chir. the following year, he held appointments as house-surgeon, house-physician, and resident obstetric officer. In 1924 he took the M.R.C.P., and proceeded M.D. a year later. He became principal medical officer to the Alliance Assurance Company and to the Imperial Life Assurance Company of Canada. He was also a senior medical examiner for the Scottish Widows' Fund and Life Assurance Society. He always loved people, and

quickly became established as a much esteemed general practitioner in London. The scrupulous and unhurried care of his patients over a period of nearly 40 years gave him an unrivalled experience of human nature and of the practice of medicine—for 20 years before the National Health Service, and as a stern critic of the N.H.S. after its inception.

It surprised no one that Lord Horder invited Hale-White to join him in founding the Fellowship for Freedom in Medicine in 1948, and to become its vice-chairman shortly afterwards. On the death of Lord Horder in 1955 he became chairman of the F.F.M., until he decided a year ago to give up the chair; he was then immediately elected its first president. From its beginning he threw himself heart and soul into the work of the Fellowship, not because he did not believe in the principle of a national health service (for he stated again and again that the Fellowship and he were in favour of making the resources and advances of medicine available to every man, woman, and child), but because he thought that since the start of the N.H.S. what used to be about the most dignified human contact, the doctor-patient relationship, had practically disappeared. He deplored that more and more the Ministry of Health seemed to think that the Service was run for the benefit of the "Elephant and Castle." His forceful way of speaking, his carefully chosen words, the transparent honesty of his views, and his great capacity for making friends made him one of the natural leaders in the medical profession—and one who was never afraid to criticize or to make constructive suggestions at meetings, in the lay press, or in the medical journals.

His record of service to the British Medical Association was substantial. From 1944 onwards he was elected year after year as a

member of the Representative Body. From 1946 to 1949 he was chairman of the St. Marylebone Division, he served on the Council of the Association from 1948 to 1957, and he was secretary of the Metropolitan Counties Branch from 1950 to 1952 and its chairman in 1955-6. He was a valued member of the Journal Committee between 1956 and 1965, and of the Private Practice Committee from 1959 to 1966. In recognition of his many services Hale-White was elected in 1964 a Fellow of the Association.

Apart from his medical activities, his great interests were painting, sculpture, and music, which gave him many hours of pleasure each week. The sympathy of all of us will go out to his widow, and to his only son.—E. C. W.

G. R. writes: Bobbie will be sadly missed and mourned by many. His patients will remember a tireless doctor who contrived to be friend and counsellor to each of them. His practice came from all walks of life, and Bobbie was somehow able to see into the hearts as well as the strictly physical problems of all his patients. Without exception they adored him. His colleagues at the B.M.A. and the F.F.M. will remember him as an ardent champion of the rights of the individual doctor. He was unsparing in his vigilance on our behalf, and yet throughout retained a real sense of humour and a great facility for words. He never overestimated his own importance, though he was always ready to help and advise and to give freely of his time. He could, and did, delegate responsibility, and if he asked you to do a job he trusted you to put into it the same enthusiasm as he would have done himself—and left you to get on with it. His many friends will miss a warm-hearted family man who never allowed his professional responsibilities to erode his private life. He loved the countryside, especially the Sussex Downs, where he made his home. He was a keen gardener and a domesticated husband. Amid his family, which included his beloved Labrador Alex, he was a relaxed and simple man. His retirement never presented him with any problems, for with his love of opera, which took him regularly to Glyndebourne and Covent Garden, and of pictures, which took him travelling, there was always more than enough to do. He was a connoisseur of good food and civilized comfort. He clearly enjoyed life to the full—a quality that was infectious—and time spent with Bobbie was always satisfying, and all too quickly passed.

W. HOFFER, PH.D., M.D., L.R.C.P.&S.ED.
L.R.F.P.S.GLASG.

Dr. W. Hoffer, a leading psychoanalyst, and consultant in psychotherapy at the Maudsley Hospital, died very suddenly in London on 25 October. He was 70.

Willi Hoffer was born in the Austrian village of Luditz on 12 September 1897, and had his schooling in Pilsen. After serving in the Austrian Army from 1915 to 1918 he entered the faculty of philosophy at Vienna University, where he read biology and psychology, the latter interest being due to the influence of August Aichhorn. He entered into personal analysis with Herman

Nunberg, and was soon launched on a psychoanalytic career. In 1922 he received his Ph.D. for a thesis entitled "The Scientific Basis of the Use of Play in Education," and in 1923 he was elected a member of the Vienna Psychoanalytical Society. He then entered the medical faculty and obtained his M.D. in 1929, after which he proceeded to spend three years in part-time work at psychiatry in Professor Otto Pötzl's department. Meantime his gifts had been recognized by his analytic colleagues, and he was given much responsible work in training and in editing. He wrote a number of psychoanalytic papers, nearly all concerned with play, childhood, and adolescence. The Nazi annexation of Austria in 1938 led Dr. and Mrs. Hoffer (herself a psychoanalyst) to migrate to England. Once again Hoffer had to undertake medical studies, as well as perfect his English, and in 1943 he obtained the triple qualification of the Scottish Colleges.

Since the second world war Hoffer came to occupy an increasingly prominent place not only in London but also in international psychoanalysis. Apart from publishing various valuable papers himself, he did much editing work. From 1945 he was co-editor of *The Psychoanalytic Study of the Child*, and from 1947 to 1959 he was editor of the *International Journal of Psycho-Analysis*. He was also a leading training analyst and teacher at the Institute of Psycho-Analysis. The very high esteem he enjoyed led to his election as president of the British Psycho-Analytical Society in 1959, a position he held until 1962. Hoffer was equally recognized in the international field, becoming a vice-president of the International Psycho-Analytical Association in 1957, and honorary vice-president in 1963. American honours included the Abraham Flexner lectureship in 1954 and his appointment as Sigmund Freud Anniversary Lecturer in New York last year.

He was appointed in 1954 consultant in psychotherapy at the Maudsley Hospital, and until his retirement from the National Health Service five years ago he contributed a great deal to broaden the postgraduate education of large numbers of registrars, with whom he was very popular. Indeed, his capacity for inspiring affection and friendship was one of his leading characteristics. What will be remembered most vividly by all who knew him is the warmth and simplicity of his personality. His many friends will miss him sorely. His wife died in 1961; there were no children.—W. H. G.

F. A. PICKWORTH, B.SC., M.B., B.S.

Dr. F. A. Pickworth, a former consultant pathologist to Birmingham hospitals, died at his home in Bournemouth on 22 October after a long and distressing illness. He was 78.

[Lotte Meitner-Grat

Frederick Alfred Pickworth, son of Dr. A. J. Pickworth, was born at Lakenheath, Suffolk, on 31 August 1889, and was educated at East Anglia School, Bury St. Edmunds. He began work as a pharmacist in Lincoln, and after serving an apprenticeship he qualified M.P.S. and finally obtained the Ph.C. in 1910. In 1913 he obtained the B.Sc. with honours in chemistry, and the following year qualified as a public analyst, after which he worked for a time as an analytical chemist. Deciding to take up medicine as a career, he entered Charing Cross Hospital Medical School and qualified with the Conjoint diploma in 1921, graduating M.B., B.S. a year later. At Charing Cross Hospital he became house-physician to Sir James Galloway and to Dr. Gordon Holmes. In 1923 he was appointed pathologist to the Birmingham Mental Hospital, and as research officer to the Joint Board of Research for Mental Diseases, working under Sir Frederick Mott. In 1926 he succeeded Sir Frederick as director of the Board of Research.

In 1935 Pickworth published his first book, *Chronic Nasal Sinusitis and its Relation to Mental Disorder*. He always gave special attention to the capillary blood supply to the brain, and developed special staining techniques which are still widely used. His major work *New Outlook on Mental Disease* was published in 1952, and he retired three years later.

In his later life Dr. Pickworth spent his time studying natural history, and was a great pond-hunter and botanist. Living as he did near the New Forest, he spent much of his time there.

In 1930 he married Jane Wylie Stocks, a medical officer at Hollymoor Mental Hospital. He is survived by his widow and three children, one of whom is a general practitioner. He will be missed by his many friends and relatives. The greatest sympathy is extended to his widow and children.—R. C. B.

W. C. FOTHERGILL, M.D., D.M.R.E.

Dr. W. C. Fothergill, a former consultant radiologist at Darlington Memorial Hospital, died suddenly on 28 September after a heart attack in the hospital with which he had been associated for 35 years. He was 67.

William Crichton Fothergill, an only child, was born in 1900 into a family with strong connexions with the Society of Friends, the medical profession, and the North Yorkshire dales. A delicate child, he was never physically robust, and took no part in sport, although he was a keen motorist in his early years and enjoyed canoeing, making trips down the Thames and Moselle in 1935. He received his medical education at Edinburgh University, graduating M.B., Ch.B. in 1923, took the D.M.R.E. in 1925, and proceeded M.D. in 1930. He held a post in Portsmouth for a time, and was senior assistant radiologist under the redoubtable Rutherford Morison in Edinburgh. In 1931 he set up practice in Darlington. He was appointed honorary radiologist to the Darlington Memorial Hospital, becoming consultant at the inception of the National Health Service. He retired from this post on reaching the age limit in 1965.

Fothergill was an amateur engineer and craftsman of considerable ability, and was an early and outstanding exponent of colour photography. Some of his early Autochrome and Dufaycolor transparencies can stand comparison with anything produced in this day of the colour slide. For many years he was a member of the Royal Photographical Society, of which he gained the associateship. He was a founder member and first president of the local camera club. A man of wide culture, he held strong views, often forcibly expressed, on a number of subjects, but basically he was shy, and one of the gentlest, most generous, thoughtful, and courteous of men.

His retiring nature prevented him from making many intimate friends, but he had a very wide circle of acquaintances who held him in high regard. They will miss his tall courtly figure and his pertinent comments on the matters of the day.—O. H. W.

J. KRUSZYNSKI, M.D.

Dr. J. Kruszyński, senior lecturer in histology in the University of Liverpool, died on 14 October, aged 64.

Jan Kruszyński was born in Poland on 12 August 1903, and studied medicine at the Stefan Batory University of Wilno. In his second year his beautiful histological drawings came to the attention of Professor J. S. Alexandrowicz, and soon led to a junior appointment to the teaching staff of the department of histology. He graduated M.D. in 1930, and attained the degree of Docent in 1936. He remained at the histology department at Wilno until he was captured by the Russians in 1939. He was a prisoner of war until 1941 and never cared to discuss his terrible experiences during that period. He joined the Polish Army in Russia in 1941, being appointed pathologist to a military hospital, with which he served as it travelled across the Caspian Sea to Italy, via Egypt, Palestine, Iraq, and Persia. He reached Britain in 1947, and was appointed assistant lecturer in histology at Liverpool in 1948, lecturer in 1950, and senior lecturer in 1963.

Jan Kruszyński was a gentle, self-effacing scholar who gave service of inestimable value to the department, and to the Medical School as a whole. He had a profound knowledge of classical histology, its literature, its methods, and results. His artistic gifts made him a superb illustrator of histological appearances; he went to untold trouble on the students' behalf in preparing demonstrations and lectures illustrated by the clearest of diagrams and drawings. He was always ready to share his wide experience of histological appearances, and was consulted by colleagues from many different departments about their problems. His own special research interest was in inorganic histochemistry; from an early stage of his career he was interested in microincineration and became recognized internationally, through lectures and published papers, as the chief authority in that field.

His hobbies reflected his artistic interests; art galleries, photography, engraving, and country walking. He will be sorely missed, not only for his professional accomplishments, but for his cheerful, modest personality and

the complete integrity of his character. Our sympathy goes to his widow.—N. M. H.

Rev. M. HATFIELD WRIGHT

M.B., CH.B., D.O.M.S.

The Reverend Hatfield Wright, formerly ophthalmic surgeon to the Swindon group of hospitals, died at his home in Liddington on 29 September. He was 69.

Morden Hatfield Wright was born on 28 December 1897. During the first world war he was a lieutenant in the Shropshire Light Infantry, and was wounded and taken prisoner in Europe in March 1918. After demobilization he entered the University of Edinburgh, where he graduated M.B., Ch.B. in 1924 and very soon afterwards married a fellow student. Both joined the Church Missionary Society and went to Gairo Hospital, combining medicine with missionary work. His 16 years in Africa were spent mostly at Omdurman Hospital in the Sudan. Much of his work was concerned with diseases of the eye, and his skill in this branch was self-taught during this period. During the second world war he joined the Army as an eye specialist, and became Southern Command senior ophthalmologist based on Wheatley Hospital, Oxford. After demobilization he took the D.O.M.S. in 1947. In 1949 he was appointed ophthalmic surgeon to the Swindon group of hospitals. He was chairman of the Swindon Division of the British Medical Association in 1960–1. He retired from his hospital appointment at the age of 65, and was ordained into the Church of England, continuing some private ophthalmic work while a curate at Liddington.

His friends and patients will remember him as a quiet, unassuming, conscientious man. Scrupulous and neat in his surgical work, he would always visit his patients afterwards, and his colleagues on the hospital staff thought highly of his work.

He leaves a widow, Dr. Mary Wright, and two daughters.—J. K. M.

N. J. L. ROLLASON, M.D.

Dr. N. J. L. Rollason, a general practitioner in Coventry for more than 40 years, died at his home in Coventry on 30 September. He was 84.

Norman John Lancelot Rollason was born in Smethwick on 6 May 1883, and was educated at Five Ways Grammar School and Birmingham University, graduating M.B., Ch.B. in 1905, and proceeding M.D. in 1908. After house appointments at the Queen's Hospital, Birmingham, he joined the late Dr. John Orton in general practice in Coventry, where he rapidly became a well-loved family doctor. During the first world war he served as a surgeon lieutenant-commander in the R.N.V.R., and from 1914 to 1964 he served continuously on committees concerned with medical administration. When he retired from active work an illuminated scroll recording his 50 years' service was presented to the executive council in the presence of the Lord Mayor of Coventry by the Coventry Local Medical Committee. During the second

world war he rendered valiant service at the time of the air raids on Coventry.

He had a distinguished record in the St. John Ambulance Association, and in 1957 was created a commander of the Venerable Order of St. John of Jerusalem. For many years he was the vicar's warden at St. Laurence's Church, Foleshill, Coventry, and secretary and treasurer of the Parochial Church Council. He loved Freemasonry, for there he felt he could relax away from his busy practice, and was a past Master of the St. John's Lodge of Freemasons and an officer of the Provincial Grand Lodge of Warwickshire. A member of the British Medical Association, he was a representative at the Annual Meeting in 1921 and 1922 and again in 1931. He was an enthusiastic angler and every holiday would be spent fishing in Scotland and later Leintwardine.

In 1908 he married Elizabeth Mary Oakden. After a wonderfully happy life together he looked after her devotedly during her last illness until she died in 1957. They had no children.—R. S. R.

H. C. MILLER, B.A., M.D.

Dr. H. C. Miller, a general practitioner at Cressage, Shropshire, died suddenly at his home in Shrewsbury on 27 October. He was 63.

Herbert Crossley Miller was born on 31 October 1903. After some years in holy orders he decided to enter the medical profession, and graduated M.B., Ch.B. from Edinburgh University in 1940. He held house appointments at Brighton, Stourbridge, and Hove. During the second world war he served for a time as surgeon-lieutenant in the Royal Naval Volunteer Reserve, but was invalided out. He then set up with his wife in general practice at Cressage, Shropshire. In addition he held an appointment at Cross Houses Hospital, near Shrewsbury, and was a justice of the peace. In 1962 he proceeded M.D., and was awarded a gold medal for his thesis entitled "The Social Medicine of an Ageing Rural Community."

J. H. F. B. writes: Dr. H. C. Miller, "Dusty" Miller to his many friends, came comparatively late to medicine; when he took up medicine in Edinburgh in 1935 he was curate at St. John's Episcopal Church, Edinburgh; aged 32 at the time, he seemed to the rest of us in the year a very senior person, indeed. He never regretted abandoning for medicine what was a career of great promise in the Church. He had tremendous gifts of warmth and personality, and inevitably became a leader among the students of his time. Like the rest of them, he was engulfed by the war and served for a time in the Navy; but was invalided out with an arthritis of the spine, which finished his aspirations to a career in surgery. He and his wife, also a doctor, set up in practice in Cressage, Shropshire, where he became the complete country practitioner, held in respect and affection by everyone, and actively involved in the life of his community. He served on the bench as a justice of the peace for many years. It was his intimate knowledge and understanding of the life of his patients which gave his book *The Ageing Countryman* the qualities of a

classic. It was based on a survey—supported by the National Corporation for the Care of Old People—of geriatric problems in rural Shropshire. Recently ill-health forced him to retire from practice; but he continued to hold a part-time appointment in geriatrics. His wife and five children survive him.

**J. A. ADAMS, B.A., M.B., B.CH.
B.A.O., L.M.**

Dr. J. A. Adams, formerly in general practice at Sowerby Bridge, Yorkshire, died in a nursing-home at Camberley on 23 October. He was 100.

John Andrew Adams was born in Ulster on 19 January 1867, and was educated at Queen's College, Galway, graduating B.A. with honours in 1888, and M.B., B.Ch., B.A.O. in 1890, obtaining the L.M. at Coombe Hospital, Dublin, in the same year. After a short period as assistant lecturer in anatomy at Queen's College, he held house appointments at the Halifax Infirmary, Yorkshire, before settling in general practice at Sowerby Bridge in the West Riding of Yorkshire, where he continued in a large practice until his retirement before the second world war. He also held the appointment of medical officer of health to Sowerby Urban District Council. A member of the British Medical Association, he was chairman of the Halifax Division from 1922 to 1924.

A.R.D.A. writes: An able and vigorous man of fine physique, Dr. Adams was held in very high regard for his professional skill and integrity and for the kindly way in which he worked. A much-respected figure, he took an active interest in local affairs, both medical and administrative. He was an active member of the B.M.A. for many years. Dr. Adams leaves behind him his devoted wife, Beatrice, and a son and two daughters.

A. W. RATTRIE, M.C., M.B., CH.B.

Dr. A. W. Rattrie, one of Cumberland's longest practising general practitioners, died in hospital at Scorton, Yorkshire, on 8 September, at the age of 82.

Alexander William Rattrie was born in 1884, and received his medical education at Edinburgh University, graduating M.B., Ch.B. in 1910. As an undergraduate he had a distinguished career, and was awarded medals in histology, pharmacology, medicine, and forensic medicine, and in addition received a major award in clinical surgery. He held house appointments at Hull, Dudley, and Wolverhampton before returning to Edinburgh to study his special interest, tuberculosis, under Professor (later Sir Robert) Philip. At the outbreak of the first world war he volunteered for service with the R.A.M.C. and was awarded the Military Cross at Cambrai in 1918 for gallantry in evacuating the wounded from an advanced dressing station while under intense shell-fire from the enemy. During this operation he himself was gassed. After demobilization with the rank of major he went into general practice, joining the late Dr. Sanderson in

Maryport in 1920. In due course Dr. Rattrie's two eldest sons joined the practice. He was a referee to the Ministry of Pensions, and examined Service recruits during the second world war. He was a life member of the B.M.A. and a founder member of the Royal College of General Practitioners and of the West Cumberland Medical Society.

On his retirement in 1965, after over 45 years of unbroken service as their general practitioner, his many grateful patients presented him with an illuminated address and cheque. Doubtless many of them recalled the years of depression in West Cumberland when, despite trying times, Dr. Rattrie still rendered them his usual dutiful attention and treatment, often without any financial reward. Those of us who were privileged to know him more personally will always remember him as a genial and generous host, a keen conversationalist, and never happier than when enjoying his occasional game of chess or bridge, both of which he played with more than average ability.

To his wife, two sons, and daughter we offer our sympathy.—J.F.

**Sir ARCHIBALD GRAY, K.C.V.O.
C.B.E., T.D., LL.D., F.R.C.P., F.R.C.S.**

Sir ARTHUR MACNALT writes: It is with sorrow that I hear of the death of Archibald Gray (obituary, 21 October, p. 178), for we had been close friends for over 60 years. When I came down from Oxford to University College Hospital to complete my medical education I was appointed clinical clerk to Sir John Rose Bradford in 1905. Gray was then his house-physician, and he taught the clerks well, not only in the wards in taking histories and examining patients but also tutorially. At noon each day he would take us into his room and interrogate us on the ward work of the morning, explaining signs and symptoms and giving valuable instruction in medicine. When in 1908 I was Bradford's house-physician Gray was resident medical officer, and was equally kind and helpful. He came of a medical family. His father was a surgeon, and he told me that one of his forebears was a naval surgeon who was present at the Battle of Navarino. Gray had a brilliant and comprehensive medical education. In addition to his knowledge of medicine he had taken the F.R.C.S., and had been a valued house-surgeon to Sir Victor Horsley. We all considered—and rightly too, I think—that he could have specialized successfully in any branch of medicine or surgery. His original intention was to be an obstetrician, and he was the first obstetric registrar to be appointed at University College Hospital. Unexpectedly, he was asked by the hospital authorities to embrace another medical career, a most unusual experience. The eminent dermatologist, Henry Radcliffe Crocker, was retiring, and there was no one to succeed him. Gray was sent to the University of Berne to study skin diseases, and on his return was appointed dermatologist to his hospital. It says much for Gray's rapid acquisition of dermatological knowledge, and for the flexibility which a sound medical education gives, that he speedily attained distinction in his new field of work.

Gray's talents and advice as a medical administrator at the War Office were most valuable to me when I was seconded from the Local Government Board to that department for inspection of camps and infectious disease hospitals and epidemiological work in the first world war. We often met both officially and socially during those anxious years. He will be sorely missed as physician, medical administrator, and loyal friend.

S.C.S. writes: In none of the several obituary notices and appreciations that have appeared about the late Sir Archibald Gray (obituary, 21 October, p. 178) is there any mention of an activity that was in his later years very dear to his heart. I refer to his connexion with St. John's Hospital for Diseases of the Skin, and to the associated Institute of Dermatology. Both of these institutions owe much to him. He was an original member of the first Board of Governors of the hospital from 1947 until 1959, and it was largely due to him that the Institute was founded in 1947. He was its chairman from its inception until 1960. During these years under his wise guidance the Institute, at first merely affiliated to the British Postgraduate Medical Federation, increased in influence and importance in dermatology until in 1957 it achieved full federation. In the years that followed, the Institute had the benefit of his unrivalled knowledge of university and medical administration. Today, two years after he finally retired from the Committee of Management, the Institute may fairly claim to have become the academic seed-bed of dermatology. Indeed, the Institute is a permanent memorial to his energy and devotion.

J.D.F. writes: It does not seem to be generally known that Sir Archibald Gray (obituary, 21 October, p. 178) had every intention of becoming a gynaecologist. In about 1908 two young gynaecologists were on the staff of University College Hospital, and there did not seem to be any likelihood of a vacancy in that specialty for many years to come. He was then gynaecological registrar at University College Hospital, and during this time he performed what I think was the first caesarean Wertheim operation ever to be carried out in England. He always had a great sympathy and understanding for the work of gynaecologists, and personally he helped me in more ways than one.

E.C. writes: When the University of London Officer Training Corps was formed in 1909 Sir Archibald (obituary, 21 October, p. 178) was one of the first to join. He recruited "C" Company, which then included men of both University College and Middlesex Hospitals. Gray told me there was soon to be a war, and I joined up as a cadet, although at the time I was doing a house appointment at U.C.H. At the very beginning, men from all faculties drilled together. The four years I served with the O.T.C., from private to sergeant, were of the greatest value to me in my subsequent 35 years of service in the R.A.M.C. and A.M.S. Gray was a keen, able, and efficient officer; many of his cadets did splendid service in the 1914 war, and subsequent years. In 1908 he was made a Fellow of University College, London, and at the time of his death was the second senior Fellow.

News and Notes

EPIDEMIOLOGY

Epidemic Keratoconjunctivitis

We are indebted to Dr. J. C. TAYLOR, of Glasgow University Department of Infectious Diseases, for the following report:

In shipyards and engineering works on the Clyde and in steelworks in Lanarkshire an epidemic of keratoconjunctivitis is in progress. A few cases occurred in July, but the epidemic situation developed in September. The peak appears to have been reached in the last week of September, and there is evidence of reduced momentum. The disease has affected metal workers mainly, but also several office workers in the industries concerned. In addition, several industrial ambulance-room attendants have been involved.

To date 27 viruses have been isolated at the Regional Virus Laboratory, Ruchill Hospital, Glasgow. These consisted of 21 strains of adenovirus type 8, 2 of adenovirus type 3, and 4 of herpes simplex virus. By serological methods evidence of recent infection with a member of the adenovirus group has been found in 36 patients. Herpes simplex virus has been found only in patients who are

not metal workers, while both strains of adenovirus type 3 were from shipyard workers. By contrast adenovirus type 8 has been isolated from 5 patients not employed in the shipbuilding or steel industries, and further epidemiological investigations are in progress. With these exceptions all strains of adenovirus type 8 and all significant titres of antibodies to adenovirus have been from employees in the shipbuilding, engineering, and steel industries.

The last epidemic of keratoconjunctivitis on Clydeside was in 1956 and was also caused by adenovirus type 8.

Narcotic Drugs

From 1965 to 1966 the number of addicts in the United Kingdom known to the Home Office increased by 422 (45.5%). The total in the latter year was 1,349. The drugs concerned were morphine and its derivatives and analogues and cocaine. Of the

1,349 addicts 886 were males and 463 were females. Of the same total 329 were aged under 20.

Between 1965 and 1966 93% of the increase in the number of known addicts was of people below the age of 35, and 90% of the increase was of addicts using heroin. The numbers of known addicts using heroin increased by 73%.

Illicit trafficking in the United Kingdom was mainly in cannabis, which was smuggled by a variety of routes. There was also smuggling of opium on a small scale. Illicit trafficking in manufactured narcotics was largely confined to small-scale peddling of heroin overprescribed by a few medical practitioners.

Approximate total quantities of narcotic drugs seized were: raw and prepared opium 17 kg., cannabis 193 kg., cannabis resin 65 kg. Convictions relating to illegal possession or use of opium numbered 36, manufactured narcotic drugs 242, and cannabis 1,102. (Report to the United Nations by Her Majesty's Government in the United Kingdom of Great Britain and Northern Ireland

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending 21 October (No. 42) and corresponding week 1966.

Figures of cases are for the countries shown and for Greater London. Figures of deaths and births are for the whole of England and Wales (London included) Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenzal pneumonia.

§ Includes puerperal pyrexia.

Codis

when pain is severe

Codis tablets provide soluble aspirin together with codeine and phenacetin. Absorption is rapid and there is less likelihood of gastric irritation during prolonged periods of administration.

In addition to the rapid analgesic and anti-inflammatory action of soluble aspirin and phenacetin, the codeine component exerts a gentle sedative effect often helpful in those cases of mild insomnia associated with pain.

Codis tablets are pleasant to take and, being administered in water, are particularly suitable for invalids and the elderly.

Codis tablets are stable over long periods of time and are presented in protective moisture-proof foil.

Basic N.H.S. price: 500 tablets 25/-.

RECKITT & SONS LIMITED, PHARMACEUTICAL DEPARTMENT, HULL, YORKSHIRE

A large, ornate glass bottle of Opilon and a glass of water. The bottle is made of clear glass with a faceted design and a stopper. It is partially filled with a dark liquid. Next to it is a simple glass filled with water.

Isn't it time
we had a truly
specific
peripheral
vasodilator?

Opilon

Such peripheral vascular disorders as Raynaud's phenomenon, chilblains, acrocyanosis or excessively cold hands and feet have always been difficult to treat decisively. Now the introduction of OPILON gives the physician specific therapy for such conditions - because OPILON blocks the vasoconstrictor effect of noradrenaline in the arterioles of the skin. Unlike other vasodilators, OPILON does not alter blood flow to skeletal muscle; and because it is solely an alpha-adrenergic receptor blocking agent it cannot directly affect the heart or general circulation. When skin ischaemia is the cause of the complaint, OPILON reliably restores circulation.

OPILON is available as tablets of thymoxamine 40 mg., in bottles of 50 and 250. Basic NHS cost 18/- for 50 tablets, 84/- for 250 tablets. **Dosage:** One 40 mg. tablet four times a day, preferably at 8 a.m., 11 a.m., 2 p.m. and 5 p.m. **Side-effects:** Occasionally mild nausea, diarrhoea, vertigo, headache and facial flushing may be encountered. These are rare, however, and transient. No serious toxic effects have been reported and the development of tolerance has not been observed. **Contra-indications:** None is known. Full information and literature will gladly be sent on request.

Opilon thymoxamine **the unique peripheral vasodilator**

on the Working of the International Treaties on Narcotic Drugs for 1966.)

Scotland in Second Quarter

The birth rate in Scotland in the second quarter of 1966 was 19 per 1,000 of the population, being 0.3 above the rate for the second quarter of 1966 but 1.1 below the average of the five preceding second quarters. The infant mortality rate was 21 and the neonatal death rate was 14 per 1,000 live births; these rates were both 2 below the rate for the corresponding quarter of 1966.

Fifty-two deaths were attributed to respiratory tuberculosis and 4 to other forms of tuberculosis; these were both 6 fewer than in the preceding second quarter. Malignant neoplasms accounted for 2,961 deaths, 79 more than in the June quarter of 1966; of these deaths 796 were due to cancer of the respiratory system, an increase of 34. Deaths from motor-vehicle accidents numbered 164 and accidents in the home 243; these were 18 and 30, respectively, fewer than in the preceding second quarter.

PARLIAMENT

Minister to Review Structure of N.H.S.

[FROM OUR PARLIAMENTARY CORRESPONDENT]

A full and careful examination of the administrative structure of the medical and related services that was needed "not only for today but looking 10 or 12 years ahead" was announced by the MINISTER OF HEALTH on 6 November.

Over the years, he said, with growing frequency the question had been asked whether the existing structure could be regarded as adequate to meet future needs. While it was wise to avoid making too early adjustments, it would be mistaken to regard as right for all time the structure which came into operation in 1948. It was particularly suitable to meet the crying need at that time, which was to reorganize, expand, and deploy the hospital and specialist services. That phase of initial reorganization was now behind them.

Scope of Inquiry

Some people said that the tripartite structure was unwieldy, and that to have three types of separate authority was not the right way to achieve that degree of integration which a proper service to the individual required. However, the nature of any changes that ought to be made required a most careful examination, and this was what he had now begun.

"I should make it clear," he stated, "that my studies will relate entirely to the administrative pattern. I am not considering the possibility of what would amount to an alternative Health Service, as is sometimes suggested, involving, for instance, a switch in financing from the public to the private sector."

Many and varied ideas had from time to time been put forward for changes. He intended to consider a number of possibilities carefully before making his own tentative

proposals. He would aim in due course, but not for some months, to set out his views, probably in the form of a Green Paper, as a basis for public discussion and wide consultation. Only after this process of consultation would the Government finally make up its mind and introduce legislation, if that was necessary.

A royal commission was studying the whole area of local government in England, and the Seeborn Committee was considering the local authority and allied personal social services. He had told these bodies of his aim to have proposals about the administration of medical and related services ready to be looked at alongside their own recommendations. He had also informed the Royal Commission on Medical Education of his intention.

LORD BALNIEL, for the Opposition, welcomed the proposed review, and asked specifically if the encouragement of private provision was not included. Mr. ROBINSON said his statement had made it clear that the review would be limited to the administrative structure of the Service.

Mr. I. MUKARDO (Poplar, Lab.) asked that the methods and criteria by which members of the various boards and committees were appointed should be considered. Mr. ROBINSON thought this would be within the scope of the structure of the Service.

Mr. E. LUBBOCK (Orpington, Lib.) welcomed the implied recognition that the tripartite structure of the Health Service was unwieldy, and asked for publication along with the Green Paper of the submissions received from interested parties, so that discussion could be as wide as possible. Mr. ROBINSON said he expected most of the submissions would be after publication of the Green Paper, because it was desirable that these should not be definitive but provisional proposals on which discussion could bite. He

agreed that greater integration was desirable if practicable.

Fewer Pay-beds

Mr. P. GRIEVE (Solihull, Con.) asked the Minister of Health on 6 November how many pay-beds were available in hospitals in England and Wales on 1 November 1966, how many were now available, and how many it was anticipated would be available on 1 January next; and for a statement of policy in this matter.

Mr. ROBINSON explained that the numbers of pay-beds available on a given day was not known centrally, and continued: "I have, however, completed my review of pay-beds, which was designed to avoid wastage of beds and make better use of them for National Health Service patients. I have informed hospital boards of my decisions. The number of pay-beds before the review was 5,764. The number now authorized is 4,379, which should meet the present demand for such beds."

Mr. GRIEVE regarded this as part of a concerted policy against pay-beds and said that if the Minister continued this campaign against private medicine he would drive more doctors out of the country. Mr. ROBINSON replied that he had made clear to the profession, and kept them informed of, the purpose and progress of the review. "I have explained to them," he said, "that the object was not to withdraw facilities from private practice but to bring about a situation in which pressure on pay-beds more clearly equals the pressure on non-pay beds."

Dr. J. DUNWOODY (Falmouth and Camborne, Lab.) commented that this meant that the use of more single-bed accommodation was being determined by medical and social reasons, rather than purely commercial ones. He asked for an assurance that this tendency would continue. Mr. ROBINSON: "I hope and believe that will be the case. It will be my policy."

Pledge on Resuscitation

Mr. ST. JOHN-STEVAS (Chelmsford, Con.) asked the Minister of Health whether he would make a statement on the policy of the National Health Service on the resuscitation of elderly patients.

Mr. K. ROBINSON: "The professional advice which I sought as a matter of urgency is that no patient should be excluded from consideration for resuscitation by reason of age or of diagnostic classification alone, without regard to all the individual circumstances. Any form of general instruction is wholly unacceptable. In each individual case the decision to attempt resuscitation must remain the responsibility of the doctor immediately

in charge of the patient.

"This advice has been made known throughout the hospital service."

Points from Parliament

► The interviewing team sponsored by the Ministry of Health (see *B.M.J.*, 30 September, p. 873) has just concluded its interviews with some 140 British doctors now working in North America who would like to return to Britain. They are being advised on their prospects of obtaining re-entry to medicine in Britain. (Minister of Health, 6 November.)

► The Government Social Survey will undertake next year a study of adults living

at home who are substantially and permanently handicapped by limitations in their movements. The survey will show the extent to which they receive and need help from local authority services, and will assist in the development of those services. (Minister of Health, 23 October.)

► In England and Wales in 1965 there were about 2,600 general medical practitioners born outside the United Kingdom and the Irish Republic; there were about 6,150 such doctors working in National Health Service hospitals. (Minister of Health, 24 October.)

► There were 20,027 unrestricted general practitioners, and 20,924 doctors working in National Health Service hospitals in 1965. (Minister of Health, 27 October.)

MEDICAL NEWS

Personal Chair of Physiology

Dr. R. C. JORDAN has been appointed to a personal chair in the department of physiology, University College, Cardiff. Dr. Jordan, who is 57, graduated B.Sc. with honours at Imperial College of Science and Technology, London, in 1930, and subsequently held D.S.I.R. and I.C.I. research appointments there in biochemistry. He was awarded the Ph.D. and diploma of Imperial College in 1933 for a thesis entitled "Metabolism of Fats and Phosphatides in *Phaseolus multiflorus*." After a further two years' bacteriological research on behalf of the Ministry of Works to investigate the role of sulphur-oxidizing organisms in the decay of the stone fabric of the Houses of

Parliament, he was appointed assistant lecturer in biochemistry at University College, Cardiff, and in succession was promoted lecturer in physiology, senior lecturer, and, finally, reader in 1961. From 1935 to 1946 he published, jointly with the late S. E. Jacobs, senior lecturer in bacteriology, Imperial College, a series of papers on the "Dynamics of Disinfection," for which he received the D.Sc.(Lond.) in 1948. About this time Dr. Jordan had his teaching appointment converted to a part-time post to enable him to undertake clinical studies in the Welsh National School of Medicine, Cardiff, and he qualified M.R.C.S., L.R.C.P. five years later. From 1955 to 1961 he was a member of the editorial board of the *Journal of Physiology*. Recently, his research interests have been in the cardiovascular field, and his group has developed new techniques for the quantitative study of spatial vector-cardiographic data and their application to the human subject under a variety of physiological and diseased conditions. Concurrently, investigations have been made in the dog on the influence of electrolyte disturbances and autonomic drugs on the relationship between intravascular pressures and cardiac electrical phenomena.

Medical Research in Scotland

On the recommendation of the Advisory Committee on Medical Research, Mr. WILLIAM ROSS, Secretary of State for Scotland, has approved support of the following medical research projects from National Health Service funds: Professor W. M. MILLAR, department of mental health, Aberdeen University, cytogenetical, biochemical, and clinical study of mental subnormality in a regional population, £9,710 for three years; Dr. W. SIRCUS, Western General Hospital, Edinburgh, clinical pathological study of ulcerative colitis, further grant of £2,100 for one year; Dr. R. J. FALLON, department of pathology, Ruchill Hospital, Glasgow, mycoplasma studies, further grant of £3,400 for three years; Dr. J. B. BROWN and Dr. P. GORDON, Currie, Midlothian, respiratory infections in general practice, £250 for three years; Dr. W. SIRCUS and Dr. I. W. PERCY-ROBB, gastrointestinal unit, Western General Hospital, Edinburgh, investigation on bile salt metabolism in ulcerative colitis, £6,600 for three years; Professor R. G. MITCHELL, department of child health, Aberdeen University, neonatal pulmonary blood flow and its variation in health and disease, £1,650 for three years; Mr. J. S. JEFFREY, Royal Infirmary, Edinburgh, tetanus prophylaxis trial, £600 for six months; Mr. G. MURDOCH, Dundee Limb Fitting Centre, Broughty Ferry, Angus, gait analysis in the amputee, up to £7,700 for three years.

Sub-dean for Postgraduate Studies

University College Hospital Medical School has established a new post of sub-dean for postgraduate studies, and Dr. G. M. STERN has been appointed the first holder of the post. The functions of the sub-dean will be (a) to arrange postgraduate seminars and discussion groups and to co-ordinate and publicize the activities of the various groups that already exist in the hospital and medical school; (b) to give advice to U.C.H. graduates on the taking of higher degrees and diplomas; (c) to assist and advise U.C.H. graduates on the availability of, and how to apply for, preregistration appointments, particularly in hospitals other than U.C.H.; (d) to follow up U.C.H. graduates in their subsequent careers, and to give advice and assistance when needed. Dr. Stern's office is in the administrative block of the medical school (Euston 5861, ext. 33).

New Hospital Buildings at Portsmouth

The Minister of Health, Mr. KENNETH ROBINSON, officially opened last week the St. Mary's Maternity Hospital and a new outpatient department at St. Mary's General Hospital, Portsmouth. The new buildings have cost about £1m. and £250,000, respectively. Referring to recent hospital development, the Minister said that in the five years ending September 1966 building schemes to the value of £223m. had been completed. This represented well over half the total for the entire period of the National Health Service. In this financial year £85m. was expected to be spent on hospital building. The figure last year was £75m. In the Wessex region a start had been made with the construction of a new district general hospital at Basingstoke. There were plans for building others at Southampton and Winchester. While a great deal had to be done to modernize the network of old and out-of-date hospitals, the building programme was being carried out at an accelerating pace.

College of G.P.s Medical Recording Service

The following titles, which may be borrowed by any doctor anywhere, have recently been added to the College of General Practitioners' library of talks recorded on tape; *Medical Negligence*, by Dr. J. LEAHY TAYLOR; *Typhoid—The Clinical Picture*, by Dr. A. MELVYN RAMSAY; *Management of Acute Renal Failure in a General Hospital*, by Dr. J. S. CAMERON; *Haemoglobin*, by Dr. HERMAN LEHMANN; *Old People's Welfare and the General Practitioner*, by Miss EVELYN ROITH; and *Drug Dependence—Recent Developments in Great Britain*, by Dr. P. H. CONNELL. A new series on teaching methods is being added to the library. Details of these talks and a list of more than 300 titles can be obtained from the College of General Practitioners' Medical Recording Service, Kitts Croft, Writtle, Chelmsford, Essex (Writtle 316).

Termination of Pregnancy

The Abortion Act, 1967, provides that any treatment for the termination of pregnancy must be carried out in a hospital vested in the Minister of Health or the Secretary of State for Scotland under the National Health Service Acts or in a place approved by the Minister or Secretary of State. Proprietors of premises who wish to have them approved for the purpose of the Act are invited to write, not later than 24 November, for forms

of application to the Ministry of Health, London S.E.1, or, if the premises are in Scotland, to the Scottish Home and Health Department, Edinburgh.

Hospital Voluntary Service

At the recent annual meeting of the National Association of Leagues of Hospital Friends the Parliamentary Secretary to the Ministry of Health, Mr. JULIAN SNOW, urged the leagues and kindred voluntary organizations to increase their visiting of old people, especially in geriatric and psychiatric hospitals. Projects for fund-raising, he said, should be undertaken only after full consultation with the hospital authority.

Medicine Related to Sport

The Institute of Sports Medicine, formed in 1963, announces that the DUKE OF EDINBURGH has accepted the presidency of the institute and that Mr. NORMAN CAPENER has become chairman in place of Sir ARTHUR PORRITT. As a co-ordinating body the institute is concerned with disseminating information, including the results of original work, initiating and promoting research, and arranging facilities for treatment. An academic board recommends and supervises research projects. The institute's address is 10 Nottingham Place, London W.1.

People in the News

► Dr. ALEXANDER HUTCHISON, medical officer of health, City of Kingston upon Hull, will be the next chairman of the council of the Royal Society of Health. He will take up office on 1 January 1968.

► Dr S. E. FINLAY, assistant medical officer, student health department at Leeds University, is to take charge of the University health service.

► Alderman A. W. BRIGGS has been appointed chairman of the South-east Metropolitan Regional Hospital Board in succession to Sir IVOR JULIAN, who retires on 31 March 1968.

News in Brief

Speaking at the annual dinner of the Royal Society of Health in London last week Mr. R. PRENTICE, Minister of Overseas Development, said that at the end of 1966 the Government was supporting nearly 1,200 doctors and nurses and other health workers overseas. British efforts, he emphasized, must be concentrated mainly on helping developing countries to provide their own trained workers.

Work is scheduled to begin in December on a new £70,000 extension to the Royal Marsden Hospital, London. When completed it will add another 16 beds to the hospital, which commemorates the centenary of the death of its founder, Dr. William Marsden, this month.

The Science Museum, London S.W.7, has set up in its atomic physics gallery a small exhibit to illustrate the nature of radioactivity, and to show how Pierre and Marie Curie discovered radium.

Grants and Awards

The Muscular Dystrophy Group of Great Britain announces that medical research grants for the 12 months beginning 1 October will amount to £126,000, an increase of 38% over the previous year.

Glasgow University has received from the Medical Research Council a grant of £3,300 over three years towards a virological study of sudden death in infancy; also a grant from the Scottish Home and Health Department of £1,300 for a further year's study of medical education on television.

The Drapers Company has contributed £1,000 towards the rebuilding of parts of the London School of Hygiene and Tropical Medicine.

In the year ended 31 July 1966 the Scottish Hospital Endowments Research Trust made grants totalling £126,072. A statement of the types of medical research supported by the Trust during the period and the names of persons who received grants are given in an appendix to the annual report (H.M.S.O., 2s. 6d.).

Recent Publications

The Wellcome Trust: Its Origin and Functions, a booklet outlining the policy under which grants are made and giving details of how applications should be submitted. Copies available from the Secretary, Wellcome Trust, 52 Queen Anne Street, London W.1.

Clinical Trials, a report to the Association of the British Pharmaceutical Industry by Dr. DAVID LONG, chief medical adviser and deputy research director of the Wellcome Foundation Ltd. Copies can be obtained from the office of the association, 162 Regent Street, London W.1.

Association of Clinical Biochemists: Scientific Report No. 3, *Automatic Dispensing Pipettes*. An assessment of 35 commercial instruments. Copies of the report can be obtained, post free, from Mr. J. T. Ireland, Biochemistry Laboratory, Alder Hey Children's Hospital, Liverpool 12, 10s. (7s. 6d. to members).

Report on *Upgrading of Wards*, 12s. 6d., Scottish Hospital Centre, Crewe Road South, Edinburgh 4.

World Health Statistics Annual, volume III, 1963: Health Personnel and Hospital Establishments, £2; volume I 1964: Vital Statistics and Causes of Death, £4. Published by World Health Organization, Geneva.

Hospital Laundry and Related Services, a second report by W. A. J. FARNDAL, Ph.D., senior lecturer in hospital administration, City of Westminster College, London. Copies can be obtained from White's Secretarial Agency, 203 Croydon Road, Beckenham, Kent, price 30s. (postage 1s. 2d.).

A booklet, *Organizations Concerned with Particular Diseases or Handicaps*, is published by the Patients Association, 335 Gray's Inn Road, London W.C.1., 2s. 6d.

Coming Events

Postgraduate Medicine, 1967 (T.V. Programme).—"Advances in Therapy," Scottish Television, 13 November (11.50 p.m.), repeat 15 November (1.10 p.m.). "Puberty," Tyne Tees Television, 14 November (1.15 p.m.), repeat 19 November (10.15 a.m.).

National Fund for Research into Crippling Diseases.—Symposium, "The Disabled Young Adult," 13 November, 9.30 a.m., Royal College of Surgeons of England. Particulars from Mr. D. Whitson, N.F.R.C.D., Vincent House, Vincent Square, London S.W.1 (01-834 7001-2).

Royal College of Surgeons of England: Faculty of Radiologists.—Postgraduate week-end course, 18 November. Fee £1 10s. Applications (with fee) to the Secretary, Faculty of Radiologists, R.C.S., Lincoln's Inn Fields, London W.C.2.

British Association of Manipulative Medicine.—Manipulation in general practice introductory course, part II, "Lumbar and Sacro-iliac Areas," 25-26 November, in London. Details from B.A.M.M., 84 Harley Street, London W.1.

Societies and Lectures

For attending lectures marked ● a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Monday, 13 November

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 5.30 p.m., clinical meeting.
INSTITUTE OF DISEASES OF THE CHEST.—6.15 p.m., Professor R. E. Steiner: Densitometry in the Study of Pulmonary Ventilation and Circulation.
INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—5.30 p.m., combined staff consultation clinical meeting.
KINGSTON-UPON-THAMES MEDICAL CENTRE.—5.15 p.m., Dr J. M. Talbot: Recent Advances in Sterilization; 6.30 p.m., Dr. E. G. J. Olsen: Embolism.●
ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Dr. W. A. Lishman: Diagnosis and Management of the Acutely Disturbed Patient.
SCOTTISH TELEVISION LTD.—11.45 p.m., *Advances in Therapy*. (Sponsored by Glasgow Postgraduate Medical Board.)

Tuesday, 14 November

B.B.C. 1 TELEVISION.—11.15 p.m. (approx.) medicine today: Low Back Pain. (Sponsored by A.S.M.E.)
BOLTON AND DISTRICT MEDICAL SOCIETY.—At Gymnasium, Bolton Royal Infirmary, 8.15 p.m., clinical meeting.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Dr. G. F. Joplin: Effects of Y-90-Phenyl Implantation in Man.
HEATHERWOOD HOSPITAL, ASCOT.—At Outpatient Hall, 8.45 p.m., Mr. C. W. Manning: Leg Inequality.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Heath Clark lecture on perspectives in health planning—I, by Dr. A. Engel (Sweden): Health Planning in a Changing Society.
MANCHESTER MEDICAL SOCIETY: SECTION OF SURGERY.—At Large Anatomy Theatre, Manchester University Medical School, 8 p.m., Mr. A. Hargreaves, Mr. N. C. Keddie: Carcinoma of the Colon and Rectum.
NEATH POSTGRADUATE MEDICAL CENTRE.—At Neath General Hospital, 4 p.m., Mr. E. Leighton John: Ulcerative Colitis.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. M. Vitali: Modern Techniques for Amputation and the Rehabilitation of Amputees.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m.,
WEST-END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. J. N. Milnes: clinical demonstration.

Wednesday, 15 November

BRITISH INSTITUTE OF RADIOLOGY.—(1) At Edward Lewis Theatre, Middlesex Hospital Medical School, 10 a.m., meeting: Design of Counting Systems for Dynamic Studies and Uptake Measurements; (2) at Institute of Child Health, 7.15 p.m., conversazione by Professor J. M. Tanner.●
CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital). (1) 12 noon, surgical meeting; (2) 8.30 p.m., Professor J. R. Trounce: Tranquillizers.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. J. Prime: The Atmosphere.
INSTITUTE OF UROLOGY.—5 p.m., Dr. A. B. Francis: Bacteriological Problems in Urology.
KENNEDY INSTITUTE OF RHEUMATOLOGY.—At rear of West London Hospital, 5 p.m., Dr. A. St. J. Dixon: Problem of Polymyalgia Rheumatica and its Differential Diagnosis.
MANCHESTER MEDICAL SOCIETY: SECTION OF PAEDIATRICS.—At Large Anatomy Theatre, Manchester University Medical School, 5 p.m., Dr. J. Blair Hartley: Some Anomalies of the Skull at Birth—significant and insignificant.
OXFORD UNIVERSITY MEDICAL SCHOOL.—At Nuffield Maternity Home Lecture Theatre, Radcliffe Infirmary, 5 p.m., Mr. W. M. Keynes: Studies in Pancreatitis.
ROYAL FREE HOSPITAL.—5.15 p.m., Dr. J. F. Soothill:
ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 11.45 a.m., clinicopathological conferences by Dr. P. J. L. Holt: Rheumatoid Arthritis; Dr. D. L. Gardner: Septicaemia. (2) 2 p.m., Dr. M. Sandler: Catecholamine Secreting Tumours.
ROYAL STATISTICAL SOCIETY.—At Botany Theatre, University College, London W.C., 3 p.m., discussion meeting: Social and Medical Statistics.
SCOTTISH TELEVISION LTD.—1 p.m., *Advances in Therapy*. (Sponsored by Glasgow Postgraduate Medical Board.)
STOKE MANDEVILLE HOSPITAL.—(1) 12.15 p.m., Dr. J. Lister: Current Views on the Management of Diabetes Mellitus. (2) 6 p.m., Squadron Leader J. P. Lee-Potter: Schistosomiasis and Leishmaniasis.
WEST MIDDLESEX HOSPITAL.—At Lecture Theatre, 5 p.m., Professor C. E. Dent: Primary, Secondary, and Tertiary Hyperparathyroidism.

Thursday, 16 November

ABERDEEN UNIVERSITY FACULTY OF MEDICINE.—At Large Lecture Theatre, University Medical Build-

ings, Foresterhill, 5 p.m., Dr. B. D. Acheson: Records, Record-linkage, and Research.
ADDENBROOKE'S HOSPITAL.—At M.R.C. Lecture Theatre, New Addenbrooke's Hospital, 8.30 p.m., Dr. M. D. A. Vickers: Does Halothane Damage the Liver?
BRITISH INSTITUTE OF RADIOLOGY.—6 p.m., discussion group; 7.30 p.m., Mackenzie Davidson memorial lecture by Professor W. V. Mayneord, F.R.S.: Radiation Carcinogenesis.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Dr. B. Creamer: Paneth Cells.
CAMBRIDGE MEDICAL SOCIETY.—7.30 p.m., visit to Technological Research Station, Spillers Ltd.
CHADWICK TRUST.—At 90 Buckingham Palace Road, London S.W. 5 p.m., paper by Professor A. L. Banks: Public Health—Balance Sheet for the Present Century.
DUNDEE UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Professor J. S. Robinson: Respiratory Failure.
HONYMAN GILLESPIE LECTURE.—At Surgery Lecture Theatre, Edinburgh Royal Infirmary, 5 p.m.,

Professor D. V. Davies: Articular Cartilage.
INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At St. Chelsea Hospital for Women, 2 p.m., Mr. H. B. Lockhart-Mummery: The Pelvic Colon and Rectum.
INSTITUTE OF RELIGION AND MEDICINE: LONDON MEDICAL GROUP.—At London Hospital Medical College, 5.30 p.m., Dr. H. Trowell: Some Problems of the Doctor-Patient Relationship.
LONDON UNIVERSITY.—(1) At London School of Hygiene and Tropical Medicine, 5.30 p.m., Heath Clark lecture on perspectives in health planning—II, by Dr. A. Engel (Sweden): Statistics and Health Planning. (2) At Edward Lewis Theatre, Middlesex Hospital Medical School, 5.30 p.m., special university lecture in pharmacology by Professor B. Holmstedt (Stockholm): Use of Gas Chromatography and Mass Spectrometry in Studies of Drugs and Metabolites.
MANCHESTER MEDICAL SOCIETY: SECTION OF ANAESTHETICS.—At Theatre B, Roscoe Building, Brunswick Street, 8 p.m., Professor J. F. Nunn: Factors in the Definition of Minimum Safe Arterial Po₂.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—At School of Pharmacy, Brunswick Square, London W.C. 7 p.m., meeting and discussion: The Sainsbury Report. Speakers include Professor A. Kekwick, Dr. G. R. Fryers.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—4.15 p.m., Arnott demonstration by Mr. R. G. Nottley: The Ureter.
ROYAL NORTHERN HOSPITAL, London.—5 p.m., Dr. C. W. H. Havard, Dr. P. Turner: Adrenergic Blockade.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 4 p.m., Dr. H. F. West: Cortisol Metabolism in Rheumatoid Disease. (2) 4 p.m., Dr. D. G. Melrose: Hypothermia. (3) 5 p.m., lecture on medical history by Dr. E. S. Clarke: The Anatomical Basis of Medicine—I.
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At London School of Hygiene and Tropical Medicine, 7.30 p.m., laboratory meeting and demonstrations.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Aleck Bourne lecture by Mr. H. Gordon: Intrauterine Transfusion.
WESTMINSTER MEDICAL SCHOOL.—At Meyerstein Lecture Theatre, 5.15 p.m., clinicopathological conference by Dr. F. B. Gibberd.

New Issues of Specialist Journals

Obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London W.C.1.

CARDIOVASCULAR RESEARCH

Contents of the October issue are as follows:

- Measurement of the Angina Threshold Using Atrial Pacing. G. E. Sowton, R. Balcon, D. Cross, and M. H. Frick.
Influence of Paired Stimulation on the Electro-mechanical Dissociation During Low Calcium Perfusion of Isolated Rat Hearts. B. S. Nieuwendijk, F. L. Meijer, and D. Durrer.
Steady and Pulsatile Energy Losses in the Systemic Circulation under Normal Conditions and in Simulated Arterial Disease. Michael F. O'Rourke.
Reduction in the Vasoconstriction Produced by Sympathetic Adrenergic Nerves During Reactive Hyperaemia. B. L. Ardill, V. M. Bhatnagar, and P. H. Pentem.
Effect of Transient Resistance Changes on Atrial Septal Defects and Other Intracardiac Shunts. R. M. McCredie.
Actions of Cardiac Glycosides on the Vessels of the Forearm and Hand. W. E. Glover, M. J. D. Hanna, and R. N. Speden.
Fine Structure of the Endocardium in Adult Rats. Haukur Melax and Thomas Sydney Leeson.
Peripheral Circulation in Hypertensive Pregnancy. Jean Ginsburg and Sheila L. B. Duncan.
Effect of Large Doses of Warfarin Sodium on Haemostasis and on ADP-induced Platelet Aggregation in vivo in the Rat. Hilary Newland and Arne Nordby.
Vasodilatation in the Canine Leg Caused by Intra-arterial Infusion of Thrombin and Tissue Thromboplastin. Anders Delin, Per Olsson, and Ann-Catrine Teger-Nilsson.
Effects of Dextran 40 on Red Cell Aggregation in Rabbits. J. Engeset, A. L. Stalker, and N. A. Matheson.
Objective Measurement of the Dispensing Effect of Dextran 40 on Red Cells from Man, Dog, and Rabbit. J. Engeset, A. L. Stalker, and N. A. Matheson.
Volume 1, No. 4. Yearly subscription (4 numbers) £3 3s., abroad £3 10s.

BRITISH JOURNAL OF OPHTHALMOLOGY

Contents of the November issue are as follows:

- Sjögren's Syndrome and Thyroid Disease. J. Williamson, J. Stanley Cant, D. K. Mason, W. R. Greig, and J. A. Boyle.
Primary Angle-closure Glaucoma. Ronald F. Lowe.
Peripheral Iridectomy in Angle-closure Glaucoma. C. I. Phillips and J. T. Snow.
Intra-ocular Pressure in Fuchs's Heterochromic Uveitis. C. T. Hart and D. M. Ward.
Congenital Glaucoma in Neonatal Rabbits. M. L. Sears.
Ocular Manifestations of Vitamin B-Complex Deficiency. G. Venkataswamy.
Waardenburg's Syndrome. J. Stanley Cant and A. J. Martin.
New Magnetic Ocular Oculorator. J. Horton Young.
Iris-clip and Irido-capsular Lens Implants (Pseudophakol). C. D. Binkhorst.
Lens Implants (Pseudophakol) Classified according to Method of Fixation. C. D. Binkhorst.
Unusual Corneal Lesion following Herpes Ophthalmicus. M. L. Sears and R. H. Fenton.
Marcus Gunn Phenomenon with Paradoxical Oculo-palpebral Movements. Hari Mohan, A. N. Gupta, and S. K. Jain.
Angle-closure Glaucoma precipitated by the Use of Phospholine Iodide for Esotropia in a Child. D. B. P. Jones and D. M. Watson.
Ophthalmological Synopses.
Lengthening of Rectus Muscles using a Special Clamp in Strabismus Surgery. G. C. Sood, S. R. K. Malik, G. Gunguli, and S. Chowdhary.
Iris Retractor. W. J. Rich.
Book Reviews.
Volume 51, No. 11. Yearly subscription (12 numbers) inland £8 8s., overseas £9. With *Ophthalmic Literature* and Index (7 numbers) inland £15, overseas £16.

THORAX

Contents of the November issue are as follows:

- Internal Surface Area and Other Measurements in Emphysema. William M. Thurlbeck.
The Use of a Cusp-bearing Homograft Patch to the Outflow Tract and Pulmonary Artery in Fallot's Tetralogy and Pulmonary Valvular Stenosis. Paul Marchand.
Experimental Aortic Valve Heterotransplantation. C. G. Duran, A. J. Gunning, and R. Whitehead.
Prolonged Treatment of Pulmonary Sarcoidosis with Corticosteroids. Clifford Hoyle, Hugh Smylie, and David Leak.
Rheumatoid Pneumoconiosis: A Study in Colliery Populations in the East Midlands Coalfield. David C. Lindars and Dewi Davies.
Asthma Due to Aluminium Soldering Flux. G. M. Sterling.
Time Factor in the Measurement of Response to Bronchodilators. G. J. Mushin.
Response of Blood Gas Tensions to Aminophylline and Isoprenaline in Patients with Asthma. E. Tai and John Read.
Impedance Pneumograph Studies in Left Ventricular Failure. A. R. Tanser.
Cyanosis with Hepatic Cirrhosis: A Case with Pulmonary Arteriovenous Shunting. A. J. Karlish, R. Marshall, Lynne Reid, and Sheila Sherlock.
Treatment of Inoperable Carcinoma of the Bronchus by Megavoltage X Rays. Thomas J. Deeley and S. Padam Singh.
Safe Per-operative Anticoagulation. J. Wiederdink.
Tracheal Stricture following Tracheostomy. P. B. Deverall.
Index.
Volume 22, No. 6. Yearly subscription (6 numbers) £4 4s., abroad £4 15s.

Friday, 17 November

BROOK GENERAL HOSPITAL.—At Postgraduate Medical Centre, 5.30 p.m., Dr. A. R. Norton: Drug Treatment in Modern Psychiatry.
KINGSTON-UPON-THAMES MEDICAL CENTRE.—1 p.m., psychiatric seminar by Dr. J. S. Bearcroft: Development of Psychiatry in the Kingston Area and Postgraduate Education in Psychiatry related to the opening of the New Psychiatric Unit at Kingston Hospital.
ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—At Newcastle-upon-Tyne, scientific meeting, morning: Observations on the Aetiology of Certain Gynaecological Cancers; afternoon: Perinatal and other Factors in the Development of Children.
ROYAL COLLEGE OF SURGEONS OF ENGLAND: FACULTY OF RADIOLOGISTS.—4.30 p.m., Skinner lecture by Dr. H. C. Ho (Hong Kong): Nasopharyngeal Carcinoma—Radiodiagnostic and Radiotherapeutic Aspects.
ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.—At Barnes Hall, Royal Society of Medicine, 2.15 p.m., Maudsley lecture by Professor A. D. B. Clarke: Learning and Human Development.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 10.15 a.m., Mr. M. Paneth: Pulmonary Embolism. (2) 11.30 a.m., Professor H. H. Bentall, Mr. W. P. Cleland: clinicopathological conference (cardiac). (3) 4 p.m., Dr. R. D. Bradley: Investigation of the Circulation in an Intensive-Care Unit.
WEST MIDDLESEX HOSPITAL.—4 p.m., Dr. Chandra Grubb: Vaginal Cytology.

Saturday, 18 November

ROYAL COLLEGE OF GENERAL PRACTITIONERS.—At B.M.A. House, London W.C.1, 11 a.m., James Mackenzie lecture by Dr. Ronald Gibson: Lucerna Pedibus Meis; 2 p.m., annual general meeting.

Sunday, 19 November

CLWYD AND DEESIDE BOARD OF POSTGRADUATE STUDIES.—At Royal Alexandra Hospital, Rhyl, 10 a.m., symposium: Diabetes Mellitus.
GREAT YARMOUTH AND DISTRICT MEDICAL CLUB.—At Northgate Hospital, Great Yarmouth, 10.15 a.m., all-day symposium: The Handicapped Child.
ROYAL COLLEGE OF GENERAL PRACTITIONERS.—At Wellcome Building, Euston Road, London N.W. 9.15 a.m., annual symposium: Combined Operations—Medicine, Science, and Humanity.
ROYAL COLLEGE OF GENERAL PRACTITIONERS: EAST ANGLIAN FACULTY.—At Papworth Hospital, 10 a.m., full-day course for general practitioners: Cardiovascular and Respiratory Conditions of Interest in General Practice.
ROYAL NORTHERN HOSPITAL, London.—10.15 a.m., clinical conference by Dr. D. Geraint James.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: *Atiology*, London W.C.1. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.

ADVERTISEMENTS AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

Pointers

Congenital Dislocation of the Hip: Technique of early detection and findings in 14,594 newborn infants described. A clinical classification for more accurate comparison of findings is suggested (p. 377). Leader this page.

Housing and Health: Service families quartered in flats had more respiratory tract infections and psychoneurotic disorders than similar families quartered in houses (p. 382). Leader p. 376.

Mumps and Endocardial Fibroelastosis: An association possible (p. 372).

Child Care: Sheldon report proposes this should become province of general practitioners (p. 374).

Gastric Emptying: Slowed by intravenous gastrin. Acid secretion rate increased and outlasts slowing of emptying (p. 386).

Choice of Stethoscope: Comparison of performance of models in common clinical use (p. 388).

Locating the Placenta: No placenta praevia missed by a colour autoscanner technique (p. 390).

Depot Corticosteroids: Tetracosactrin—a synthetic preparation—maintains its activity twice as long as a gelatin preparation of natural corticotrophin, is easier to inject, but causes more local discomfort (p. 391).

Cushing's Syndrome or Obesity? Fluorimetric estimation of urinary 11-hydroxycorticoids is a relatively simple and rapid procedure for differentiating these two conditions (p. 394).

Case Reports: Tuberous sclerosis and retinopathy (p. 398); stellate ganglion block in total blindness (p. 400); scorbutic megaloblastic anaemia (p. 402).

Postgastrectomy Syndromes: Current Practice article reviews the abdominal complications (p. 403).

Immunization: Review of Sir Graham Wilson's book on its hazards (p. 407).

First Blood Transfusion: Sir Geoffrey Keynes reviews the rival claims of London and Paris (p. 410).

Hospital Organization: Suggestions for shortening waiting-lists, using private beds and local benevolence, and more realistic accounting (p. 411).

Middle-age: Its disabilities reviewed (p. 414).

Artificial Sweeteners: Ministerial assurances on cyclamates (p. 429).

Assistants and Young Practitioners: Want general practitioners to have hospital beds (*Supplement*, p. 53).

Fellowship for Freedom in Medicine: Addressed by Labour M.P. (*Supplement*, p. 55).

Congenital Dislocation of the Hip

One of the most rapid recent advances in medicine has been in the diagnosis and treatment of congenital dislocation of the hip. In 1961 a leading article in the *B.M.J.*¹ stated that late diagnosis was still a major problem and cited the results of treatment of children 3 years old and of a few up to 5 years old. In 58% of cases satisfactory results followed conservative treatment; open reduction had to be performed in 20% of children with this disorder under 3 years old.

Since then a new conception of the nature of congenital dislocation of the hip has replaced the old ideas, which originated in the days of Hippocrates and were elaborated by Dupuytren and others, all of whom thought the condition incurable. In 1936 M. Ortolani² described a test, subsequently modified by other workers, to check the state of the hips of newborn children and to detect congenital dislocation of the hip at birth.³

In an article at page 377 of the *B.M.J.* this week Dr. H. V. L. Finlay, Mr. R. H. Maudsley, and Mr. P. I. Busfield describe this test in detail. Widespread use of it by many hospital workers has convinced most observers that all congenital dislocations are present at birth. The condition is "congenital" only in this sense; it is not a genetic defect in the same class as the developmental errors like harelip, cleft palate, and absent or supernumerary fingers, but is probably an acquired condition occurring in the last few weeks of pregnancy. The figures so far published indicate that there is a noticeable reduction of incidence in children under 4½ lb. (2,000 g.) in weight at birth; and if it were a true developmental error the incidence ought to be the same irrespective of birth weight or its related factor, maturity. Further observations and serial examinations of very young children from birth to one week old show that undue laxity of the hips, from the smallest degree up to complete dislocation, is far more common in newborn children than was believed a few years ago, and that in the first week of life there is a high rate of spontaneous recovery—approaching 60% in fact. These discoveries, together with the opportunities of early treatment that early diagnosis affords, have in a matter of a few years brought the success rate of conservative treatment very close to 100% and reduced the operation rate (adductor tenotomy) to less than 5%.

Here surely is one of the most satisfying things in medicine. The diagnostic test is simple, requires no special skill, no special apparatus, and can be carried out by the doctor or midwife at the mother's bedside immediately the child is born. There is virtually no risk of fracturing a healthy femur if it is accorded the gentleness and care normally extended to newborn babies. In fact there is a far greater risk of the child sustaining a fractured femur during birth, especially a breech birth, than there is in examining the hips. The interpretation of the test is simple. The child is placed in the position described in the article by Dr. Finlay and his colleagues: in a normal hip the femur and the pelvis move together. When the femoral head is slowly moved backwards the pelvis rotates with

it, because the femoral head is in the acetabulum and stays in the acetabulum. In a dislocated hip the femoral head is clearly seen to be moving backwards and forwards on the side of the pelvis; the pelvis does not rotate with it. This movement is accompanied by visible lengthening and shortening of the thigh and by the palpable click described by Ortolani. There is hardly a simpler test in the whole of medicine. On the discovery of such a hip it would seem permissible to wait and then re-examine the child in seven to ten days. If there still appears to be an abnormality the child should be placed on a splint.

Dr. Finlay and colleagues sum up the present position accurately, precisely, and clearly. They make an important point in drawing attention to the apparent variation in incidence in different parts of the country. There may be a true geographical variation, but the apparent incidence in a place will depend to some extent on the skill and experience of the examiner, for the more experienced examiner

will tend to recognize more of the less affected hips. The apparent incidence may also vary owing to lack of uniformity in the definition of the various states of the hip. These authors have produced a comprehensive classification of abnormalities of the hip covering every state of laxity in the newborn baby, including those conditions which are not true congenital dislocations but are teratological and paralytic in origin.

This is a valuable contribution to the already extensive literature on the subject. Examination of the hips for congenital dislocation should become automatic for every doctor who sees newborn or very young babies. The results of treatment after diagnosis at birth are so nearly perfect that crippling from congenital dislocation of the hip should soon recede into medical history.

Mumps and Cardiac Embryopathy

Just over 200 years ago Morgagni¹ described a case of "endokardfibrosen." It was probably one of the first reported cases of the cardiac anomaly about which so much was written in later years and for which in 1943 T. Weinberg and A. J. Himelfarb² suggested the name endocardial fibroelastosis. The primary form of endocardial fibroelastosis usually presents with heart failure and cardiomegaly in the first year of life. The aetiology is unknown, but recent evidence suggests that intrauterine infection with mumps may be connected with this syndrome.

A few years ago G. R. Noren and associates³ made the interesting observation that nine children with primary endocardial fibroelastosis showed a delayed-type cutaneous hypersensitivity reaction to mumps virus antigen. More recently J. W. St. Geme, G. R. Noren, and P. Adams⁴ report further observations on this interesting relationship. Fourteen children aged 2 months to 2 years in whom a diagnosis of primary endocardial fibroelastosis had been made were tested by intradermal inoculation with 0.1 ml. formalinized mumps antigen prepared in embryonated hens' eggs. All 14 children developed erythema 10 to 15 mm. in diameter within 24 to 48 hours; one child reacted to both the mumps and the control antigens. Only 2 of the 14 children had detectable mumps neutralizing antibody at the time of the skin test and one of them had been exposed to mumps after birth. In a control group of 25 children of the same age range only 4 developed a skin reaction of 10 mm. or greater; six showed a reaction of 5 to 8 mm., and the remainder either had no reaction or one of 3 to 4 mm. One child reacted to both mumps and control antigens to an equal degree. None of the 25 control children were found to have mumps antibody. Similar tests on the mothers of the children with endocardial fibroelastosis showed that all reacted to the mumps antigen to the usual degree that is expected in those who have contracted natural infection with mumps—that is to say, 15 to 25 mm. Six of these mothers gave a history of exposure to mumps in the first trimester of pregnancy and of having had parotitis as children, whereas none of the mothers of the control group of children did so.

Retrospective inquiries have their disadvantages, but nevertheless these observations cannot be lightly dismissed. Further tests on the children with primary endocardial fibroelastosis gave additional information. Eight of the seronegative children in the endocardial group were tested again after one or more skin tests with mumps antigen in an attempt to detect an anamnestic antibody response, but none gave it. Three of the children were also inoculated with 1.0 ml. of inactivated mumps vaccine. Only one of these developed an antibody response. Punch biopsies from the erythematous skin reactions showed a mononuclear-cell type of response, characteristic of delayed hypersensitivity reactions. Positive transfer of lymphocytes in one of the patients produced a delayed reaction in a previously non-responsive child. Attempts to isolate mumps virus from the hearts of fatal cases were unsuccessful.

Similar studies have been carried out by several other groups of investigators. A co-operative study,⁵ from the Hospital for Sick Children, Toronto, and from Rochester, N.Y., using defined criteria,⁶ produced essentially similar findings on cases of primary endocardial fibroelastosis. Out of 50 children with primary disease aged 0 to 5 years, 42 developed a positive skin reaction of 10 mm. or more of erythema within 24 to 36 hours at the site of inoculation. In the age group 0 to 2 years, which was similar to that studied in the Minneapolis survey, 91% (19 children) were positive. In the control group of 138 children 91% had a negative skin test. J. B. Vosburgh and associates⁷ at the University of Kansas reported positive skin reactions in six out of nine children with primary endocardial fibroelastosis aged 15 to 54 months. But studies conducted from the Children's Hospital Medical Center in Boston have failed to substantiate these findings. W. N. Gersony and associates⁸ could find no evidence of a relationship between endocardial fibroelastosis and mumps on the basis of exposure to mumps in pregnancy, presence of mumps serum antibody, or a positive skin test. However, these authors regarded an erythema of 15 mm. or greater as positive and 10 to 14 mm. as doubtful.

What then is the significance of these findings? Despite contradictory results the relationship between mumps and fibroelastosis cannot be ignored, certainly not on the question

of a millimetre or two of erythema. A verdict of "not proven" would appear to be justified in these circumstances, and this should lead to further investigations. One of the first points to be established is the question of what constitutes a positive reaction. The recommendations of the American Public Health Association and the manufacturers of the antigen state that the minimal area for a positive skin test is 15 mm. and that one of 10 to 14 mm. should be regarded as doubtful. But these recommendations are based on studies of mumps infection in children and adults acquired postnatally. No information is yet available on whether an infant exposed to mumps in utero will react in the same way.

If it is accepted as a working hypothesis that there is some aetiological relationship between maternal mumps and fibroelastosis, how can one explain the findings of a delayed-type hypersensitivity reaction and absence of mumps antibody? The situation is very different from what occurs after foetal infection with rubella and cytomegaloviruses. In both these cases virus persists for long periods and a high titre of neutralizing antibody is produced, but it is not yet known whether infants who have had congenital rubella show a hypersensitivity reaction or not. In trying to visualize a possible mechanism to explain the difference between the effect of rubella and cytomegaloviruses and the possible effect of mumps on the foetus, it may be relevant to note that the former result from primary infections of the mother (certainly this is true of the great majority of cases of rubella), whereas in some of the cases of fibroelastosis a history was obtained of the mother's re-exposure to mumps in pregnancy after an attack of the disease in childhood. It is theoretically possible that a delayed hypersensitivity reaction could develop in the foetus as a result of an interaction, possibly of short duration, between mumps antigen and mumps antibody derived from the mother. Experimental evidence shows that delayed hypersensitivity can be induced without development of circulating antibody. It is also possible to explain this reaction on the basis of cross-reactivity with another myxovirus, such as one of the parainfluenza viruses, but no evidence for this could be obtained.⁴

More clues might be found in a prospective study of mumps in pregnancy, including both primary infections and cases of re-exposure, with a detailed clinical and virological assessment of the offspring. Particular attention would have to be paid to accurate recording of the mumps skin test in terms of millimetres of erythema. But the possibility of a multiple causation of endocardial fibroelastosis must be borne in mind. Recently L. Fruhling and colleagues⁹ produced evidence of Coxsackie B virus infection with recovery of Coxsackie virus from the myocardium of several children with fibroelastosis. More recently still G. C. Brown and T. N. Evans¹⁰ provided serological evidence that Coxsackie virus infection contracted in the first trimester might be causally related to congenital

heart disease. Further work may show the extent to which mumps, Coxsackie, and other viruses are related to congenital malformations.

Hazards of Ambulance Journeys

Though the prime function of an ambulance service is to carry patients, it must also provide special care for the 5% of them who are emergency cases. As emergency treatment has become increasingly successful in saving lives that would previously have been lost, the importance of getting the patient quickly to the therapeutic team is clear. But two closely connected questions arise here. One concerns the therapeutic facilities that should be available to the patient before he reaches hospital, the other the manner of his transport. Recently the report¹ of a working party to the Ministry of Health and Scottish Home and Health Department has made a number of useful recommendations on ambulance design and equipment.

C. R. G. Howard² and K. C. Easton³ among others have called for skilled medical attention to be available at the scene of the accident. Though this cannot always be practicable, there are occasions when it may be—for instance, in country districts with specially enthusiastic and knowledgeable practitioners. (In towns the shorter journey means that calling a doctor may delay the movement of a patient to hospital.) In other circumstances a special team can sometimes be summoned from a suitable hospital,⁴⁻⁶ as when a person is trapped and needs resuscitation. And, again, where accidents are predictable—at motor races, for example—the necessary facilities can be prepared in advance. J. F. Pantridge and J. S. Geddes⁷ have recently reported on the value of a mobile intensive-care unit that can be quickly got to a patient with myocardial infarction.

At present too little information has been published on what happens to patients before they reach hospital. This would seem to be a deficiency worth remedying. Certainly it is difficult to lay down rules for deciding when a patient should be moved from the place of the emergency, how he should be moved, and whither. When special knowledge is lacking, humanity and common sense may suffice, and there is no doubt that ambulance crews in different parts of the country are continually making wise decisions in difficult cases. But better radio communication is needed between ambulances and emergency units—for even experienced men appreciate guidance and those that are less so need it. Moreover, it is valuable if calls for help can be assessed by an experienced doctor.

An ambulance for dealing with emergencies should allow a single patient to be carried in the middle so that attendants

have ready access to him from all sides; it should have space for equipment; and it should provide a comfortable ride. Of these requirements the last is more easily stated than achieved. Even for a healthy person it is at least disconcerting to ride recumbent in an ambulance, without the sight of surroundings that would enable him to brace himself when necessary. For sick and injured people such unpleasantness fades into insignificance beside the jolting and swaying of which correspondents have recently written in the *B.M.J.*⁸⁻¹⁴ Even a good road, a modern ambulance, a considerate driver, and a police escort do not guarantee a smooth ride. P. W. Bothwell¹⁵ has long campaigned in the cause of devoting as much care to the suspension of ambulances as to that of racing cars, but manufacturers need some financial incentive, for Britain has only a few hundred new ambulances of all types each year. Meanwhile the Working Party has provided admirable specifications as a guide to local authorities requiring to order new ambulances or to refurbish existing ones.

Escherichia coli Pneumonia

It has long been recognized that antibiotic treatment is altering the bacterial aetiology of nonspecific infections. Those caused by organisms, such as haemolytic streptococci and pneumococci, consistently and highly sensitive to antibiotics are either less common or at least less often assume their severest forms, notably septicaemia. On the other hand, staphylococci and various coliform bacilli, which can be highly resistant to many antibiotics, have come into far greater prominence as causes of life-endangering infections. This has nowhere been made clearer than in the studies of M. Finland and his colleagues¹ in 1959, who showed that septicaemia due largely to Gram-negative species was actually causing a higher mortality than that from old-fashioned forms in the days before either antibiotics or sulphonamides had been introduced.

Many infections of this kind are acquired in hospital, and some are "superinfections" replacing another organism eliminated by the antibiotic used in treatment. This is particularly true of infections of the lung. With the exception of *Klebsiella pneumoniae* (Friedländer's bacillus), which is a rare cause of severe lobar pneumonia, Gram-negative organisms have not been regarded as primary pathogens in the lung, but only as "opportunists." Certainly Gram-negative organisms have not in the past been recognized as causing any pneumonia with distinctive characters. The claim of J. R. Tillotson and A. M. Lerner,² of the Detroit Général (Receiving) Hospital, to have observed a distinctive type of pneumonia caused by *E. coli* must therefore command interest. This hospital serves a predominantly negro population. During a period of 30 months it admitted 1,882 patients with pneumonia: in 81 of these the cause was a Gram-negative bacillus and in 20 this was *E. coli*.

The mean age of these patients was 53, but was higher in the 11 whites than in the negroes; 12 were men. "One or more serious chronic diseases were present in every case"; among many mentioned are diabetes (11), pyelonephritis (11), alcoholism (7), arteriosclerotic vascular disease, anaemia, hypertension, pancreatitis, and peptic ulcer. It thus seems

unlikely that this form of pneumonia can occur in a previously healthy subject. The condition was considered to have developed before admission in 15. The organism, usually found in more than one site, was cultivated from the sputum in 18, from the blood and urine in eight patients each, and from pleural exudate in six. The lesion was a lower lobe bronchopneumonia with a predominantly mononuclear alveolar exudate, often complicated by empyema. Oddly enough, this complication was a favourable prognostic sign: the overall mortality was 60%, but only 37.5% in eight patients with empyema and 75% in those without. Tachycardia was disproportionate to fever and hypotension was common. Herpes labialis was never seen. The infection was considered to have arisen in either the urinary or gastrointestinal tracts, the former in the eight patients with pyelonephritis, and the latter sometimes after gastroenteritis or abdominal operations: aspiration may have been responsible in two. No evidence for these assumptions about origin is offered.

All the patients were treated with antibiotics. The antibiotic used had been shown to be appropriate by laboratory tests in all survivors, but in only two out of the 12 fatal cases. Kanamycin was the most successful; when chloramphenicol and tetracycline were used resistance developed rapidly in repeated cultures from several sources. Tillotson and Lerner suggest that the resistance was due to the operation of transference, but they made no attempt to establish whether this was the explanation. This is perhaps unfortunate, for the finding is unusual, and it is difficult to see how organisms in the blood or urinary tract, where other bacteria would not usually have been present, could have acquired resistance in this way.

There is no reason for supposing that this disease entity is peculiar to the country in which it has been described, though it may well be largely confined to indigent people in whom serious chronic disease has been neglected. Physicians elsewhere may find it rewarding to watch for *E. coli* pneumonia, but if they do so their laboratories should be warned to take more interest than usual in what are commonly dismissed as "coliforms."

Health of the Child

From its inception the National Health Service has been criticized for its tripartite structure. In particular the accusation has often been made that the N.H.S. consists of two sickness services—those provided by the hospitals and by the general practitioners—and that only the services provided by the local authorities can be described as a health service.

In 1964 a subcommittee of the Standing Medical Advisory Committee under the chairmanship of Sir Wilfrid Sheldon was set up "to review the medical functions and medical staffing of child welfare centres and to make recommendations." The subcommittee might have advocated a strengthening of the local authority health services, which would have led to further trichotomy and to increased dissipation of already scarce medical manpower. Instead its report¹ takes a refreshing and realistic look at the subject, and challenges the hospital and general medical services to take more interest in the health of children.

Few doctors doubt that provision for the maintenance of health, prevention of illness, and the early identification and

¹ Finland, M., Jones, W. F., and Barnes, M. W., *J. Amer. med. Ass.*, 1959, 170, 2188.

² Tillotson, J. R., and Lerner, A. M., *New Engl. J. Med.*, 1967, 277, 115.

correction of disease would result in a more healthy society. Moreover, in theory, this should eventually reduce the demand on the curative services. The problem is to decide how the preventive services should be provided. The subcommittee thinks that the general care of infants and children should become the province of general practitioners supported by health visitors, and that the hospitals should provide centres for special assessments and treatment. The medical officer of health should continue to be responsible for the overall supervision of the services for children, and for ensuring that they are adequate.

Many general practitioners have already shown that they can successfully provide in their own premises many of the services described in the report. Several of them have described their experiences in holding infant welfare clinics and health education classes in the surgery, in co-operating with health visitors, and in doing routine school health service examinations. Nevertheless, so far this work has been carried out by enthusiasts, and it can be done only with the aid of an equally enthusiastic and co-operative medical officer of health. Several problems will have to be solved before general practitioners can undertake work in this field. Many are already so burdened with work that they might be unwilling or unable to accept further responsibilities. Not all surgeries have space where clinics could be held, or a room in which a health visitor could work. The holding by general practitioners of clinics, other than in their own premises for their own patients, might be resented by some of their colleagues. Many family doctors would want to have further training in paediatrics and to know more of the skills and training of health visitors and other workers in the health team. The subcommittee was precluded by its terms of reference from making financial recommendations, and thus it forbore to make the obvious point that general practitioners should be paid for this work.

The best way to resolve most of these problems would be for groups of doctors to work from specially designed premises. When one or two members of a group or partnership follow a personal interest jealousies and fears of poaching patients need not arise. The work load might well be eased by more recruitment to general practice from married women and others now employed by local authorities. They might be attracted by the prospect of working part or full time in a group where they could also practise their special skills. Younger doctors would be more inclined to become general practitioners if they knew that they could do good work in good premises.

The Subcommittee underlines the need for changes and improvements in the teaching of child care both for undergraduates and for graduates, and it advocates inclusion of child care in the vocational training of all general practitioners. The Royal College of General Practitioners has advocated at least three, and preferably six, months' vocational training in paediatrics. The subcommittee rightly suggests that principals who wish to undertake the work now carried out for children by local authorities should undertake thorough postgraduate training. At present this would require special payments, as the length of time suggested (six weeks) would not be covered by the existing arrangements under Section 48 of the National Health Act. Payments would also have to be made for locum cover during the absence of the doctors concerned.

¹ *Child Welfare Centres, Report of the Subcommittee, Standing Medical Advisory Committee, Central Health Services Council, Ministry of Health, 1967. H.M.S.O., London. 4s. 3d. net.*

Views are changing on the whole content and organization of general practice. The recommendations of the Sheldon Committee are sensible and they should find general acceptance. Above all they would offer family doctors a chance to enlarge the scope of their work in a field which is properly theirs. It is a chance they should not miss.

Diagnostic Value of Fluorescent Antibodies

The reaction of humoral antibody with its specific antigen is classically detected by precipitation if the antigen is in solution, by agglutination if it is particulate, by lysis if it is cellular, or by the ability of the antigen-antibody complex to fix complement. To detect the distribution of an antigen histologically A. H. Coons and M. H. Kaplan¹ devised and developed a technique for labelling specific antibodies with a fluorescent dye so that histological preparations treated with the conjugate, and thoroughly washed to remove unbound reagent, showed the sites of antigen by their fluorescence on examination with light of appropriate wavelength.

Though the principle of the procedure is simple, in practice the method presents many technical difficulties in the avoidance of false positive reactions. These can be considerably reduced, firstly, by the separation of the immunoglobulin fraction from the serum proteins as a whole by making use of salt fractionation or column chromatography, and secondly by the careful removal of unbound dye, usually by passage of the conjugate through a column of Sephadex G.25. Finally, the tendency of the conjugate to bind to the tissues non-specifically can be largely avoided by absorption with a dried powder of liver or other tissue known to lack the antigen under investigation.

The method is not confined to the study of antigens. By the use of labelled antigens it can as readily be applied to the histological demonstration of specific antibody.² Both these types of procedure in which the specific reagent is itself labelled employ what is known as the direct fluorescent technique. Its major drawback is the necessity for a different labelled reagent for each antigen or antibody under investigation. Much more versatile is the indirect or so-called sandwich technique,³ in which a single reagent can be employed for the study of an indefinite range of antigens and their antibodies. For example, if one wishes to study the distribution of 20 different antigens in a guinea-pig by means of 20 specific antibodies raised in rabbits, it is not necessary to label any of the specific antisera, since their presence in a histological preparation can be as clearly shown by the use of a single labelled antibody to rabbit immunoglobulin prepared in some other species such as goat or sheep. Thus the distribution of type III pneumococcal polysaccharide injected into a guinea-pig is detected by treating appropriately prepared sections firstly with a rabbit antipneumococcal type III antiserum and then by the fluorescent goat antirabbit immunoglobulin antiserum. The rabbit immunoglobulins

bound by the type III polysaccharide will then in their turn bind the fluorescein-labelled goat antirabbit globulin. Any antigen therefore against which a rabbit antiserum is available can be demonstrated by a single fluorescent preparation of goat or sheep antirabbit immunoglobulin antiserum.

Of the many applications of the fluorescent-antibody technique now in use some of the most useful are in the identification of micro-organisms and the detection of specific antibodies in suspected cases of infection.⁴ In syphilis, for example, the treponema fluorescent antibody test is proving of great value,⁵ comparable to the immobilization test. All that is required is an acetone-fixed preparation of the Nichols strain of *Treponema pallidum* and a fluorescent antihuman immunoglobulin serum. If the patient's serum under test contains antibodies to the treponema, the application of the fluorescent antiserum will reveal the organisms by the characteristic fluorescence of the conjugated dye. An ever-widening field of application is also to be found in the study of autoimmunity and autoimmune disease.⁶

The successful use on a large scale of fluorescent-antibody methods in clinical pathology will depend, however, on a commercially available supply of reliable, standardized preparations of fluorescent antibodies. At least one such preparation now appears to have been developed for the purpose of rapidly identifying viral diseases.

Living in Flats

The problem of housing Britain's expanding population is bound to intensify in the next two decades. Indeed, many people are now asking how best to provide acceptable dwellings while retaining sufficient land for industry, agriculture, recreation, and communications. Consequently it would seem that a higher proportion of flats is likely to be built than has been customary in the past.

It is generally believed that families living in high flats are exposed to certain medico-social hazards. More recently, as local housing authorities outside the big cities increasingly turn from traditional houses to flats of three or four stories, it is being suggested that life in low flats can also present its problems. Now Wing-Commander D. M. Fanning in a paper at page 382 of this issue of the *B.M.J.* has performed a useful service by making an ingenious study of a substantial number of armed Forces families living in such flats. He provided an adequate control group, and he was able to eliminate the major variables. Measurements of the comparative incidence of illness are more difficult to choose. The number of consultations a patient has during a particular illness may depend on many factors, not all relevant to its severity, and objective assessment of severity was not practicable in the circumstances of Wing-Commander Fanning's survey. The choice of "first consultation rate" was thus

probably wise, though this too has its deficiencies as a measure.

The figures showed that flat-dwellers had 57% more morbidity (as measured by the seeking of medical advice) than dwellers in houses. Hospital admissions were much the same in the two groups, but referrals to specialists showed the same disparity as first consultations. One might infer from this that while the incidence of serious disease was unaffected the flat-dwellers tended to present rather more complicated clinical pictures. The flat-dwellers' higher rate of sickness was most marked in diseases of the allergic endocrine-metabolic group, the nervous system and sense organs, the respiratory system, the genito-urinary system, the mental and psychoneurotic group, and the skin and cellular tissue group. The only significant groups in which the house-dwellers showed a higher morbidity were disorders of bones and organs of movement, and accidents.

The largest of all the groups was respiratory illness, with among the flat-dwellers three times as many patients as any other. Fanning reasonably suggests that lack of open-air exercise might contribute to this type of illness. This would be consistent with the finding that there was a small but steady increase in the incidence of respiratory disorders as the height of the flat increased. The young children, especially those aged 5-9 years, were the most frequent sufferers, and in this context it would have been interesting to have an analysis of the types of disorder. Could the disparity have been related to emotional stress? Fanning's discussion of social factors makes it clear that a substantial number of the conditions which lead to emotional stress—notably monotony, boredom and isolation, and difficulty in looking after the children—were present, and he may well be right in his surmise that the comparatively small number of patients with psychoneurotic disorders were only the tip of an iceberg. In these last, also, the incidence was greater among people living in the higher flats.

One difficulty about using first consultation as a measure of sickness is that what has been called the "surrender point" cannot be excluded. The decision to seek medical advice is a deliberate one. The patient, or the parent of the child patient, is sufficiently disturbed by the symptoms of the disease to acknowledge illness and to accept the inconvenience, effort, and worry which that acknowledgement may entail. The more active and interesting a person's life, the less a particular symptom is likely to obtrude. The bored, the isolated, and the irritated may not be more ill but simply *feel* more so. Does this explain at least part of the greater morbidity among dwellers in flats than in houses?

From the immediate clinical point of view this may not be very important. What patients seek from the doctor is first and foremost relief from their symptoms. It may, however, be important in long-term prevention, when the community has to decide between providing fewer flats, providing better flats, and preparing flat-dwellers for a new type of living.

Dislocatable Hip and Dislocated Hip in the Newborn Infant

H. V. L. FINLAY,* M.B., F.R.C.P.ED., M.R.C.P.; R. H. MAUDSLEY,† M.B., F.R.C.S.; P. I. BUSFIELD,† F.R.C.S.

Brit. med. J., 1967, 4, 377-381

Congenital dislocation of the hip produces, if untreated, an obvious and tragic disability. The results of treatment are profoundly affected by the age at which the condition is first diagnosed. In recent years increasing emphasis has been placed on routine examination of newborn infants in order to detect those conditions of the hip that might precede established dislocation. It is claimed that if such hips were splinted in abduction for the first few weeks of life established dislocation would be largely or entirely prevented. These claims were vigorously prophesied by Roser in 1879, though his own wide experience of dislocated hips was confined to infants over the age of 1 year. We began a study of the problem in 1961, and now report the findings.

Ortolani (1937) focused attention on the fact that instability of a child's hip joint could be detected on clinical examination, though Roser (1879) had noted that there were older infants with loose hip joints which could be dislocated by adducting the thighs and which could be reduced again by abduction. Andrén and Borglin (1960) thought that this instability might result from laxity of the hip capsule produced by maternal hormones, as they had found that analysis of urine from newborn infants with congenital dislocation of the hip indicated a disorder of oestrogen metabolism. Andrén (1960) also showed that the pubic symphysis may share in this laxity.

Starting in 1952, von Rosen (1962, 1963), of Malmö, found 68 cases of clinically diagnosed "congenital hip-joint dislocation" among a total of 31,200 newborn infants—an incidence of 2.2 per 1,000. Of those, 53 were girls and 15 were boys. He showed that the routine splinting of such hips in abduction for some weeks resulted in normal joints. He further claimed that, as a consequence of such splinting, established cases of congenital hip dislocation were no longer appearing in the community where he worked.

Coleman (1956), in Salt Lake City, examined the hips of 3,500 newborn infants during a period of 10 months, and found 30 babies with "congenital dysplasia" of the hip on physical examination alone, by showing either a "jerk of exit" or persistent and unequivocal limitation of abduction of the flexed hip.

Palmén (1957, 1961), in Sweden, reported the application of the Ortolani test to 12,394 newborn infants he had examined from 1950 to 1960. From 1956 onwards this test was complemented with a "subluxation provocation." In all, 70 cases with positive signs were diagnosed and were treated immediately with fixation in abduction on a wooden board. In most cases the infants were examined on one occasion between the first and fourth days of life. At a re-examination in 1961, out of 39 infants abnormal at birth, who were by then at least 3 years old, one had dysplastic changes and two showed the results of capital necrosis. Palmén had instigated in 1953 the routine examination of the hips of all newborn infants

at the majority of obstetric clinics in Sweden having paediatric consultants. Up to and including 1960 the survey had covered approximately 415,500 newborn infants, representing 49.5% of all children born alive in Sweden during this period.

Later Barlow (1962, 1963, 1966), of Salford, was able to confirm von Rosen's work. He started his series in 1957. Examining the babies within a week of birth, he found 357 abnormal hips out of a total of 19,625 infants. Of these, 168 were frankly dislocated hips and the remaining 189 dislocatable. Only six of the abnormal hips in the series occurred among the infants weighing less than 5 lb. (2,270 g.) at birth. Barlow also claimed that of the children whose hips were regarded as normal when examined at birth only three had later been found to have a dislocated hip.

Among 6,000 newborn infants examined from 1958 to 1962 Stanisavljevic (1964) found a positive Ortolani sign in 29. Ten had bilateral and 19 unilateral signs. Four of these babies were not treated for 6 to 10 months after birth, and none improved spontaneously. Twenty were treated with Frejka pillows immediately after birth until the age of 3 months, and at 6-8 months the hips of all these babies were found to be normal on clinical and radiographic examination.

Writing from Tel-Aviv, Weissman and Salama (1966) reported that the Ortolani sign was present in 45 out of 16,841 infants born alive during the three years 1962-4. The average and practically constant incidence for the whole period was 2.7 per 1,000.

Present Investigation

In the Duchess of Kent Maternity Wing at Hillingdon Hospital in the summer of 1961 we began a survey of all the newborn live infants, who were examined to determine the state of the hip joints. A separate survey sheet was filled in for each infant. All the initial examinations were carried out by members of the paediatric team, so that there was some uniformity in the assessment. Virtually all the initial examinations took place within 36 hours of birth.

Method of Examination

The examination was performed in a manner similar to the method described by Barlow (1961). The infant was examined lying supine in the cot. The bedclothes were always spread completely flat. The hands were warmed and the infant was approached gently in an effort to obtain general muscular relaxation. The position of the head of the femur was first carefully noted with the infant at rest and before the hip was passively moved. The infant's knee was acutely flexed, and this enabled the head of the femur to be grasped between the examiner's thumb anteriorly and his fingers posteriorly. An attempt was now made to move each femoral head in turn gently forwards into or backwards out of the acetabulum. After

* Paediatric Unit, Hillingdon Hospital, Uxbridge, Middlesex.

† Orthopaedic Unit, Hillingdon Hospital, Uxbridge, Middlesex.

the peculiar clonking sensation of the femoral head clearly jolting in and out of the acetabulum had once been experienced by the examiner, this sign of instability of the hip joint became quite unmistakable and case-finding much more reliable.

The child's femora were then gently abducted simultaneously. During the first two days of life maximum abduction usually approaches 90° from the vertical, and this degree normally decreases slightly over the next few days. Abduction is markedly impaired in the case of an established dislocation of the hip of the teratological type. It is also impaired in cases of dislocated hip with lax capsule, but the act of abduction itself readily tends to reduce such a joint. Thus the abduction test in the newborn infant has severe limitations diagnostically, and it must be sensitively carried out.

It must be stressed that in all these manoeuvres the head of the femur was grasped in the manner described and the knees were not held at all. This safely reduces the leverage effect, when combined with gentle handling and lack of hurry. It is common during the first few hours after birth to find that, with the baby lying supine, this manoeuvre may initiate regurgitation of stomach contents with choking, so that mucus suction may be necessary.

Classification

The widely differing statistics from different observers may be partly due to race, climate, and other factors, but are also due to the differing criteria of what constitutes "dislocation." Some are based on Ortolani's test or its modifications. Some, such as "dysplasia," are based on radiological criteria.

Dexterity in examination may detect a larger percentage of dislocatable hips. Each hip of an infant may fall into differing groups at the time of examination, and, owing to progressive changes taking place over the first few days of life, a hip joint may fall into one group one day and into another on the next day. The terms "slack hip," "lax hip," or "unstable hip" may not mean precisely the same entity to different observers.

The following classification of the clinical state of the hip joint in the newborn infant is suggested as a means of comparing accurately the findings in different centres.

Newborn Infant's Hip—A Classification

Normal Hip : Group A

Group A1 : Stable and Abducts Fully.—The hip joint is stable and abducts fully.

Group A2 : Stable with Lack of Abduction but no Dislocation.—The hip joint is stable, but shows a moderate limitation of abduction. The radiograph is normal and the adductor tightness apparently bears no relation to dislocation in these cases. Stanisavljevic (1964) found nine such infants with limited abduction in a series of 395 newborn babies. Without treatment, at the age of 14 months a clinical and x-ray follow-up showed no abnormality.

Group A3 : Crepitant or with Ligamentous Click.—The hip joint is stable but on attempting to dislocate the head backwards out of the acetabulum a clicking noise may be heard, or a slight crepitant, crunching, or grating sensation felt by the examiner. This has been termed "the crepitation of ligamentous origin" (Parkkulainen and Solonen, 1959), and arises from a flattened or oval-sectioned ligamentum teres rotating under the femoral head or from other tendons moving over each other in the region of the greater trochanter (Barlow, 1966). Such cases are so common that they must be regarded as within normal limits. Unfortunately infants in this group

may erroneously be thought to have the "clicking sign," and for this reason the term should be abandoned.

Group A4 : Lax but not Dislocatable.—There is more laxity of the capsule than usual, with increased mobility of the femoral head, which, however, cannot be completely moved out of the acetabulum. We have splinted four such cases, probably unnecessarily. Such hips we now regard as within normal limits. It is clear that this intermediate group—deliberately placed within the normal group—represents a minor degree of the same condition found in the dislocatable group. Certain infants may have one hip in this group while the other may be dislocatable or dislocated.

Unstable Hip : Group B

Group B1 : Dislocatable but in Normal Position at Rest.—This hip lies in a normal position at rest, but is dislocatable. The femoral head can readily be dislocated out of the acetabulum by pressing the femoral head backwards so that the characteristic clonk is felt. Full abduction can always be obtained. Infants in this group during the first day or two after birth may then pass into the lax but not dislocatable group A4. If untreated, probably the majority would remain in the normal position.

Group B2 : Dislocated at Rest but can be Reduced.—The hip lies in the dislocated position at rest, but can be reduced, readily in most instances, by pressing the femoral head forwards. On gently abducting the femur the range of abduction is limited up to the point when reduction is made to occur and then full abduction can be attained. The joint capsule is lax and the femoral head can readily be dislocated backwards again. If untreated, there is a considerable risk of the dislocation persisting. The dislocatable and this dislocated group again represent differing severities of the same condition.

Pathological Hip : Group C

Group C1 : Dislocated but Not Reducible by Palpation and Not Associated with Other Congenital Abnormalities.—This group corresponds to the older infants with established, untreated dislocation. Partly because the infants in our series were examined so soon after birth we encountered no neonatal example of this type, but in one case of dislocated hip of unstable type we were able to reduce the joint only with some difficulty.

Group C2 : Teratological Dislocation.—There are gross lack of abduction and the classical signs of dislocation of the hip. The femoral head cannot be readily replaced in the acetabulum, and such cases cannot be controlled by the Barlow or modified von Rosen type of splint. There is an association with arthrogryposis or other congenital abnormalities. As well as being clinically distinct, the majority in this group are also likely to be entirely separate aetiologically. These cases have been termed "teratological" by several writers.

Group C3 : Dislocation Associated with Meningomyelocele.—The hip joint is dislocated in association with a meningo-myelocele. These cases merit a separate group as they present in a distinct way, and the hip-joint dislocation is usually the least of the child's disabilities.

Radiographs

Andrén and von Rosen (1958) showed that, if radiographs of the hip joint were taken with the femora internally rotated and abducted to at least 45°, dislocation of the unfossified head could be demonstrated by the alignment of the femoral shaft in the newborn infant with an unstable hip. This technique has been used and commended by Jacobs (1966), who reported

the radiographic findings in a Birmingham series. Only during the early part of the investigation did we routinely take radiographs of children whose hip joints were thought to be abnormal in the newborn period, since we soon appreciated that the diagnosis in the unstable groups was basically a clinical one and radiographs had not added to our information in these groups. Palmén (1961) also regarded as unnecessary the x-ray examination of these cases before beginning treatment. Radiographs have proved most helpful in other groups. We have more recently preferred to avoid exposure to radiation in the unstable groups except for follow-up control.

Even during the follow-up examinations interpretation of the radiographs has sometimes proved difficult, especially during the months until the femoral head has become clearly ossified. A slight degree of pelvic tilt or rotation can produce a misleading radiological view of the hip joint.

Treatment

The first cases of unstable hip which we discovered were treated initially by full hip abduction, using several layers of napkins secured by a pin at each side until a Frejka pillow or suitable splint was provided. This thick napkin method proved unsatisfactory, as it did not have a sustained effect, and, indeed, gave a false sense of security.

For the last three years of the series the von Rosen splint in a modified form (see Illustration) was routinely applied within four days of birth, and we now have three sizes available even for the neonate. Various slight modifications have been made from time to time. The metal framework of duralumin must satisfy the twin needs of strength and correct malleability. The rubber covering formerly used has now been replaced by a white washable vynide covering which is less irritating to the skin of some infants. The seams of this covering have been specially sited away from pressure points. By angulating the crossbar so that it has a shallow vertical groove in the midline, pressure on the spine can be avoided. The shoulder pieces of the splint must be set at an optimum angle, while the leg extensions must not abrade the medial skin of the thigh above each knee.

Modified type of von Rosen splint used in present series

This splint is reasonably well tolerated and has enabled us to maintain satisfactory abduction. Inevitably both hips are affected by the splint. The child is not removed from the splint, except for adjustments, for a period of three months. In a few of our cases, particularly the small premature infants, the application of the splint had to be postponed owing to poor general condition after birth.

We now regard all the infants in our group A as requiring no treatment.

Results of Present Neonatal Study

During the latter part of 1961 the results of routine hip examinations in our unit were difficult to determine because of uncertainty in examination techniques.

In the five-year period 1962–6 a total of 14,594 infants were born alive in the unit. The hips of all were examined, except in the few instances when death occurred very soon after birth. Apart from two cases of dislocated hip of teratological type (born in 1964 and 1965 respectively), and all cases of meningocele, a total of 60 children were discovered who had a clearly dislocatable or dislocated hip (Table I). Of these 60, 13 were male and 47 female. In 21 instances the hips were bilaterally affected, but in several of these one hip was dislocatable while the other was dislocated at rest. In six infants the right hip only was affected, and in 33 the left hip only. Breech presentation and/or a history of version accounted for 13 (22%) out of the 60 cases. The overall breech delivery rate in the unit was 4%.

TABLE I.—Infants with Dislocatable or Dislocated Hips of Unstable Type, 1962–6

Year	Total Live Births	Total with Dislocatable or Dislocated Hips of Unstable Type	Male	Female	Right Only	Left Only	Bilateral	Birth Weight above 5½ lb. (2,500 g.)	Birth Weight 5½ lb. (2,500 g.) or Less	Breech or History of Version
1962	2,791	8	0	8	1	5	2	8	0	1

The series includes three singleton siblings, all from the same Indian family—in each instance the initial examiner was not at the time aware of the family history. The mother of another affected infant had been operated on at the age of 2 years for congenital dislocation of the hip.

The more detailed findings on initial examination of the 30 cases seen during the last two years of the study are set out in Table II. In 15 of these infants one or both hips were dislocated; in 20 infants one or both hips were dislocatable. During the last two years these 30 cases represent an incidence of 1 in 193 infants—that is, 5 per 1,000 live births.

We have excluded from the series those newborn babies with abnormal hips who were not actually born in the unit.

Follow-up Study

Of the 60 cases in the series, two died during the neonatal period and two failed to attend as outpatients.

The remaining 56 were followed up in the orthopaedic clinic, either at our hospital or, in the case of eight babies, at some stage at other hospitals. In four children born during 1962–3 dislocation was not prevented, and these required further attention—two of these were premature infants with birth weights of 4 lb. 2 oz. and 3 lb. 6 oz. (1,870 g. and 1,530 g.) respectively.

At the end of the series all the patients still living locally were asked to attend for a detailed follow-up survey, and 37 were seen. Those born in 1966 who attended were over the age of 6 months when examined. The radiographs were studied particularly for evidence of dysplasia or necrosis of the femoral head. In one child born in 1963, and aged 3½ years when examined, the affected hip showed no clinical or radiological evidence of dislocation, but there was an irregularity of the trabecular pattern of the upper femoral metaphysis.

In two cases the question of dislocation remained radiologically doubtful for several months, but the hips were radiologically normal on final follow-up examination.

The overall results of the follow-up, which includes information received from other hospitals, are summarized in Table III.

TABLE III.—Overall Follow-up Study of 60 Infants with Dislocatable or Dislocated Hips of Unstable Type

Year	Total	Died in Neonatal Period	Not Available for Follow-up Beyond the Neonatal Period	Dislocation Persisted and Further Treatment Required	Satisfactory and Followed up but not Seen Beyond Age 6 Months	No Clinical or Radiological Evidence of Dislocation on Follow-up Beyond Age 6 Months
1962	8	1	0	1	1	5
1963	10	0	0	3	0	7
1964	12	1	1	0	2	8
1965	14	0	0	0	1	13
1966	16	0	1	0	1	14
Total	60	2	2	4	5	47

Six months after the last child in our series was born we obtained the active co-operation of 134 family doctors who replied to our letters of inquiry about cases of hip dislocation, and whose practices lay partly or wholly in the area surrounding the hospital. This inquiry brought to light one female infant, born in our unit in 1962, whose hips were passed as normal when examined on the day after birth. At the age of 11 months a diagnosis of benign congenital hypotonia was made at another hospital. At the age of 2 years and 9 months the left hip was found to be frankly dislocated, and an open reduction was later successfully carried out.

So far we have been unable to trace any patients with established dislocation of the hip unassociated with other disease who had been born in our unit during the period 1962–6 and whose hips had been passed as normal on neonatal examination.

Discussion

Careful examination of the hip joints in all newborn infants is already being widely carried out in this country. The results are of great interest, but it is important to assess their value critically, as there are still those who are sceptical. From a purely statistical point of view it is unfortunate that the natural incidence of established congenital dislocation of the hip is so low. Firm conclusions are difficult to reach unless large numbers of newborn infants are available for study. The differing criteria of various clinicians have in the past made comparison difficult.

Such routine examinations would be justified if it could be shown that the majority, if not all, of the potential cases of congenital dislocation of the hip were included within the unstable groups with either dislocatable or dislocated hips—a conclusion strongly suggested by our inquiries and follow-up studies.

It is also most desirable that a large number of babies should not be subjected to unnecessary splinting, for, though the splint is kept on for an average of only three months, it creates considerable parental anxiety and concern as well as some discomfort for the infant. There is a potential risk of inhalation of feeds, and breast-feeding may be made more difficult.

In addition there is the question whether such apparently simple routine treatment may cause damage to the joint. Allen

(1962) reviewed the radiographs and records of 150 children who had been seen during a period of 10 years with an original diagnosis of "hip dysplasia," based on the finding of an acetabular angle greater than 30° as seen radiologically. No dislocation was demonstrated at any time in these patients. Some were left untreated, some were treated with Frejka pillows, and others were manipulated and then held in 90° abduction casts or apparatus. Radiological evidence of ischaemic necrosis had developed subsequently in 14 children—each of these had been treated with a 90° cast except one who was in a 90° apparatus without plaster. Allen pointed to the danger of making a cripple out of a normal child. This has not been our experience. It is only fair to add that Denis Browne (1961) thought that so-called fragmentation of the head of the femur or avascular necrosis were terms used to describe a purely temporary effect which occurs fairly often in cases treated by controlled movement.

It is not easy to assess accurately the number of established cases which would have resulted in our series if no treatment had been given. That certain races have a higher incidence of congenital dislocation of the hip than others is well known. There were 148 cases among children born in Birmingham in the years 1942–52. This gives an incidence of 0.65 per 1,000 live births. Though this may be slightly below the true value it is probably acceptable as an estimate of incidence among children who survived infancy (Record and Edwards, 1958). Many would accept an incidence of 0.7–1 per 1,000 for Great Britain up until 10 years ago.

Out of the total number of infants examined 10.5% were the children of Indian immigrants. Out of the 60 cases of unstable hip of either dislocatable or dislocated type eight were Indian, but this figure includes three siblings all in the same Indian family. We can assume that within the 14,594 infants born during the period under our study there would finally have resulted at least 12 cases of established dislocation of the hip (including those of teratological type). This means that possibly three or four children were being subjected to unnecessary splinting for every one child who was saved from the development of established dislocation.

Over the last two years of the series, when the neonatal incidence was 5 per 1,000, four out of every five children were in retrospect unnecessarily splinted. What is needed is some means of differentiating those cases with unstable hips in the neonatal period which are most at risk. It is tempting to suggest a policy of "wait and see"—to re-examine abnormal hips at the age of 1 week and splint only those that are still abnormal. The history of our unsuccessful cases does not encourage us in this view.

Sayle-Creer and Barlow (1960) made a careful distinction between dislocatable hips and dislocated hips, though to some extent it may be fortuitous, depending largely on the position of the legs, whether the hip is in or out of joint at the time of the neonatal examination. We have encountered several infants with a dislocatable hip within 24 hours of birth who within two days showed such a rapid lessening of joint laxity that they fell into the lax but not dislocatable group. It might be logical to splint those in the dislocatable group for a shorter period—for example, two months—than those in the already dislocated group—for example, three months.

As there is a tendency for unstable hip joints to become progressively more stable during the first 10 days of life, the earlier the infants are examined in a series the higher will be the incidence of unstable hips discovered. It is stressed that in our series virtually all the infants were first examined within 36 hours of birth, and the majority within 24 hours. Barlow (1962), reporting the first 9,000 newborn infants in his series examined at a weekly clinic, found that the half that were under 3½ days old produced 100 babies with 112 abnormal hips. In the half who were 3½ to 7 days old he found only 39 with 47 abnormal hips.

The tendency of the neonatal hip joint to become progressively more stable is one of several reasons for considering that groups A4, B1, B2, and C1 indicate advancing degrees of joint capsule laxity. In almost all infants the degree of joint laxity already present apparently decreases from the hour of birth. On theoretical grounds, mild laxity would be expected to disappear with the joint in correct position, but pronounced initial laxity would carry a greater risk of the joint remaining in the dislocated position. This accords with the fact that the earlier cases with pronounced instability are splinted with the hip joint in its correct position the better are the results.

The possibility should be borne in mind that repeated clinical examination may itself produce changes in the joint. We have personally examined a few of the infants with a readily dislocatable hip, and then carried out re-examination within a few hours, only to find in some an almost stable joint showing a moderate degree of palpable periarticular thickening. This suggests that the manipulation involved in testing the joint may on occasion produce a local reactive oedema. When this occurs it is important that the joint should not be left in the dislocated position—a valid reason for applying a splint without delay once the diagnosis is made.

The part played by the position of the child in utero is emphasized by the number with breech presentation, and also by the significantly small proportion of cases showing involvement of the right hip alone.

It is of interest to compare our findings in a series at risk with those of Record and Edwards (1958), who studied a large series of cases of established dislocation of the hip in the city of Birmingham. The sex ratio in their series was 85% female—in the present series it was 78%; including their bilateral cases, the left hip was affected in 80% of the cases—in the present series 90%; 17% were associated with breech deliveries—in the present series 22%. Only 4.2% of their series had associated defects of the nervous system. The incidence among their children born in the winter was double that of children born in the summer, and the risk of a subsequent child being affected was about 5%. Such a series would also include those presenting neonatally as teratological in type, with various other malformations. Von Rosen (1963) in fact excluded two such cases from his neonatal series.

The term "congenital hip dysplasia" was introduced by Hilgenreiner, of Prague, in 1925. A review of the literature shows that in the past this label has embraced many infants whose hips we would regard as entirely within normal limits.

The series published by Coleman (1956), Palmén (1961), Barlow (1963), and Stanisavljevic (1964) are of particular value, as the newborn infants in each series were personally examined by the same individual. In our own experience there is no doubt that our case-finding of abnormal hips would have been higher if carried out in this way, instead of by a trained team with careful checking by one of us of abnormalities found. Nevertheless, our figures give some idea of what may be attained by the routine examination of the hips as standard practice by a paediatric team in a neonatal unit.

We have excluded from our series cases of congenital dislocation of the hip associated with meningocele. For the purpose of comparing findings in the newborn infants with those in established untreated cases, it is wise to exclude also those in the special teratological group, though the latter are usually included in published series referring to older children.

Summary

In the five-year period 1962–6 a total of 14,594 infants were born alive in a single maternity department. Except in the few instances when death occurred very soon after birth, the hips of all were examined within 36 hours of birth. The condition of the hip joint was specifically noted on a survey

sheet in each case. All the examinations were carried out as a routine by a member of the paediatric team. Excluding two cases of dislocation of the teratological type and all cases of meningocele, 60 infants with clearly dislocatable or dislocated hips were discovered. The female preponderance was nearly 4 to 1. Approximately one-third were bilaterally affected, and in the remainder the left hip was 5.5 times more often involved than the right. In 22% of the cases there had been a breech delivery. During the last two years of the study the incidence of neonates with dislocatable or dislocated hips of unstable type was 5 per 1,000, and in half of these infants the hip was dislocated.

A clinical classification of the state of the hip joint in the newborn infant is suggested, with reasonably clear-cut groups as a mean of comparing accurately the findings in different centres.

The technique of clinical examination of the hip joints within 36 hours of birth is given in detail, and should be a routine procedure, as it can lead to the prevention of established dislocation, at least in the great majority. At present this involves the splinting of approximately four cases which would spontaneously stabilize for every one case which would finally remain dislocated. The implications of this are discussed. Splinting of the hips in abduction should be carefully confined to infants who are at real risk, and in these the splint should be applied within four days of birth if possible. In our series a von Rosen type splint proved satisfactory, and it was kept on the infant for an average period of three months.

Details are given of the follow-up investigation carried out on the children with abnormal hips. Two infants died in the neonatal period and two were not available for follow-up. Owing to inadequate or late splinting in the earlier cases of the series, four cases of dislocation were not prevented, and these required further attention.

We wish to thank all members of the paediatric team who assisted in this survey, and we greatly appreciate the co-operation of the local family doctors.

We are grateful to Dr. S. M. Tucker for the inclusion of several of the 1966 cases, and to those orthopaedic surgeons who have kindly sent us follow-up information about infants who have subsequently come under their care. Our thanks are also due to Miss S. G. Ward and Miss T. E. Turner for their secretarial assistance.

The von Rosen type splint was supplied by Mr. J. Drew, 443 Uxbridge Road, Ealing, London W.5.

Families in Flats

D. M. FANNING,* O.B.E., M.B., B.S., D.P.H.

Brit. med. J., 1967, 4, 382-386

The fact that poor housing affects the health of the community has been understood since the time of Chadwick, but the ways in which housing can affect health, and the nature of the ill-health which may be caused by unsatisfactory housing, have changed. Over the past 25 years the health of people living in new towns and on new housing estates has been shown in several instances to be poorer than might have been expected, in spite of the improvements which have occurred in their sanitary environment.

Much of the blame for this has been ascribed to social factors, such as those described by Young and Willmott (1962) in their account of the movement of families from Bethnal Green to a new estate outside London, thus breaking their family links. Brotherston and Chave (1956) described a higher rate of attendance on their general practitioners by people who lived on a new housing estate than might have been expected; and Martin, Brotherston, and Chave (1957) found that the incidence of neurosis on a new housing estate was 77% in excess of the national average. Taylor and Chave (1964) described how on a new housing estate they found that there was a lowered threshold for consulting a doctor, which resulted in a higher rate of overt neurosis.

The effect of the adverse environment of new housing estates is well documented, but that of another phenomenon of modern housing development—namely, the building of blocks of multi-storeyed flats in large numbers—is not. Hird (1966) found an increase in illness in flats. He stated that in flat dwellers he found twice as many upper respiratory infections in children below the age of 10 as there were in house dwellers, and that he had twice as many consultations in which symptoms of emotional disturbance predominated.

It would appear that people who live in new housing estates and in new blocks of flats are often poorer in health than those who live in older and hygienically less satisfactory types of accommodation, even though the design and appointment of the new dwellings are thought to be greatly superior to the old. The morbidity which occurred among the families of some members of the armed Forces living in modern flats and houses in Germany was examined in order to compare the health of those who lived in the flats with those who occupied houses.

Scope of Survey

The records of 558 families were examined in detail over a period of 10 weeks from 30 August to 6 November 1965, including the practice records concerning attendances, referral for specialist opinion, and domicile of the patient. The families were chosen because they lived in two well-defined and comparable areas—one an estate of houses, similar in design and layout to a modern local authority estate, and the other an estate which was composed of three- and four-storey blocks of flats, also comparable with a similar arrangement in England. The period was relatively short, but was kept so in order to minimize the number of families who moved during the study. In fact, during the 10 weeks eight families moved away, and were replaced by another eight whose size, age, and sex distribution

were sufficiently similar not to affect the composition of the population.

All medical attendances were known to the practice, as it was in the circumstances the only one available, and all contact with the local hospital was arranged through it. The community was self-contained and self-sufficient, with all the amenities that are found on a well-developed housing estate in England, all services such as schools, churches, shops, buses, and entertainment being readily available. A time was chosen when attendances were neither markedly more nor less than usual, and there was no epidemic of infectious disease current. Attendances for the whole practice during 1965 included 11,187 consultations with a general practitioner from a population which averaged 2,480, a consultation rate of 4.51 per registered patient in the year. In the section which was studied there were 1,409 consultations with a general practitioner from the 1,608 patients over the 10-week period, which was equivalent to an annual rate of 4.56.

The section of the practice which was chosen had the following attributes: (1) They were all families of non-commissioned ranks; that is, in the same social class and income group. Though they were unclassified in the 1966 General Register Office Classification of Occupations, they were placed in class III in the 1950 classification. (2) Only those who were in a flat or a house by chance rather than by choice were included. The usual system was one of allocation of the next available dwelling to the family at the top of the waiting-list, but there were some exceptions to this, and these were excluded from the study. (3) Social facilities were comparable; that is, buses, schools, shops, and medical services were equally available. (4) They all came under the care of the same practice. This applied to the wives and children, but not to the men, who were therefore not included in the study. (5) They were all within walking distance of a doctor's surgery.

The age distribution of the two groups, which is shown in Table I, was sufficiently alike to permit comparison. The mean number of children per family in flats was 1.9 and in houses 1.8.

TABLE I.—Age Distribution of Populations in Flats and Houses

Age Group:	0-4	5-9	10-19	20-29	30-39	40+	Total
No. living in flats ..	374	250	143	232	128	36	1,163
" " " houses	121	85	77	77	50	35	445

The houses were of modern design, soundly built, and two-storeyed, in short terraces with a common front and individual back gardens, with two or three bedrooms, and centrally heated throughout. The flats were in blocks of three or four storeys, well laid-out in an open space with grass surrounds, with two or three bedrooms, and also centrally heated. Group A, living in 398 flats, comprised 1,163 women and children, and group B, living in 160 houses, 445 women and children.

Measurement of Morbidity

Most studies of illness in general practice use the total number of consultations with the doctor as a measurement of morbidity. It is felt that as the number of times that a doctor may see a

* Wing Commander, Royal Air Force.

patient with any particular illness may vary with his personal preference, clinical methods, experience, or work load, or with factors imposed by the patient, a more precise measurement of morbidity is obtained by using a "first consultation rate," as described in the Registrar General's subcommittee report on measurement of morbidity (1954). This measurement is that of the number of first consultations for an illness or disease during a defined period, related to the average number of persons exposed to risk during that period. As, particularly in the case of respiratory infections, any patient may attend with more than one illness during a specified period, the number of patients consulting a general practitioner during the 10-week period of the survey has also been recorded. Both these measurements have been used to compare the women and children who lived in flats with those who lived in houses. The number exposed to risk is taken as the population at the beginning of the survey.

Differences in Types of Illness

The total number of first attendances, referrals to specialists, and admissions to hospital is shown in Table II.

TABLE II.—Attendances by Families From Flats and Houses Over the 10-Week Period

	Group A: Flats			Group B: Houses		
	No. of Patients Attending	No. of First Attendances	Rate per 1,000 in Group	No. of Patients Attending	No. of First Attendances	Rate per 1,000 in Group
First attendance by G.P. for any reason ..	672	696	598.5	162	170	382.0
Referred to specialist ..	81	81	69.6	19	19	42.7
Admitted to hospital ..	25	25	21.5	11	11	24.7

The differences in the rates of first attendance by the general practitioners show an increase of morbidity of 57% in those families who lived in flats compared with those who lived in houses, and the difference in the rates at which they were referred for specialist opinion was 63%. The proportion admitted to hospital was nearly the same in both groups, and this may indicate that though the amount of illness in the flats was greater than that in the houses, the degree of seriousness was not.

The nature of the increased morbidity was established by classifying the diagnoses made according to the World Health Organization *International Classification of Diseases*, and this is shown in Table III. The most frequent diagnosis in both groups was of disease of the respiratory system; 35.1% of all illnesses seen in patients from flats, and 26.5% in those from houses, fell into this category. The difference between the incidence in the two groups is significant at the level of $P < 0.01$ if a χ^2 test is applied. The predominant illness was infection of the upper respiratory tract, but it is interesting to note that a diagnosis of bronchitis or of pneumonia was made in 14 instances in patients who lived in houses, and 66 times in those who lived in flats, which represents incidences of 31.5 and 56.7 per 1,000 respectively, the difference between which is significant at the level of $P < 0.05$. A similar difference ($P < 0.05$) was seen in the incidence of disorders of the nervous system and sense organs, which were partly related to the respiratory diseases, as they included cases presenting as acute otitis media which were precipitated by nasopharyngeal infection.

Genitourinary disorders were more than twice as common in women who lived in flats as they were in those in houses, the most frequent form being a menstrual irregularity. The doctors concerned were all of the opinion that they were associated with the incidence of psychoneurotic disorders,

which were twice as frequent in flats as they were in houses, and the differences in incidence in each case are significant at the level of $P < 0.05$.

There was one significant difference where the incidence of a group of disorders was higher in the families in houses than it was in those who lived in flats—namely, those which fell

TABLE III.—Comparison of Rates of First Attendance by General Practitioners on Both Groups, According to the Diagnoses Made

Disease Group	Group A: Flats			Group B: Houses		
	No. of Patients Consulting	No. of First Attendances	Rate per 1,000 in Group	No. of Patients Consulting	No. of First Attendances	Rate per 1,000 in Group
I. Infective and parasitic ..	18	18	15.5	6	6	13.5
III. Allergic, endocrine, and metabolic ..	23	23	19.8	3	3	6.7
IV. Blood disorders ..	4	4	3.4	4	4	8.9
V. Mental and psychoneurotic ..	42	42	36.1	8	8	17.9

XI. Complications of pregnancy ..	5	5	4.3	2	2	4.5
XII. Skin and cellular tissue ..	31	32	27.5	7	7	15.7
XIII. Bones and organs of movement ..	11	11	9.5	11	11	24.7
XVI. Unknown and undiagnosed ..	65	71	61.0	12	13	29.2
XVIII. Accidents ..	26	26	22.4	16	16	35.9
XVIII. Non-sickness ..	28	28	24.1	10	10	22.5
Total ..	672	696	598.5	162	170	382.0

into the group of disorders of the bones and organs of movement, which were more than twice as frequent in women in houses, and under which heading were collected a variety of diagnoses, the most frequent being the low-back-strain syndrome ($P < 0.05$).

Differences Between Age Groups

Some age groups showed a greater difference in the incidence of sickness between flats and houses than others, and this is shown in Table IV.

TABLE IV.—Differences in Rates of First Consultation With the General Practitioners Between Those Living in Flats and Those in Houses, by Age Groups

Age Group	Group A: Flats			Group B: Houses		
	No. of Patients Consulting	No. of First Consultations	Rate per 1,000 in Age Group	No. of Patients Consulting	No. of First Consultations	Rate per 1,000 in Age Group
0-4	232	250	668.4	47	53	438.0
5-9	123	125	500.0	24	26	305.9
10-19	58	59	412.6	18	19	233.8
20-29	165	166	715.5	39	39	506.5
30-39	74	75	585.9	22	22	440.0
40+	20	21	583.3	12	12	342.9
Total ..	672	696	598.5	162	170	382.0

With the children there was a higher sickness rate in those under 5 years in both groups than in their older siblings, as might be expected, but there was a marked difference between those in all age groups who lived in flats and those who lived in houses. With the women, the greatest difference between flat- and house-dwellers was in those of 40 years and over, and in those in their twenties, with a much smaller difference between those in their thirties. The major difference in sickness

rates between the children from the flats and those from houses was seen in the incidence of respiratory disorders in those under the age of 10. This difference narrowed in those aged from 10 to 19, but increased again slightly in the young mothers of 20 to 29, as is shown in Table V.

TABLE V.—*Differences in Rates of First Consultation With the General Practitioners for Disorders of the Respiratory Tract Between Those Living in Flats and Those in Houses, by Age Group*

Age Group	Group A: Flats		Group B: Houses	
	No. of First Attendances	Rate per 1,000 in Age Group	No. of First Attendances	Rate per 1,000 in Age Group
0-4	134	358.3	26	214.9
5-9	60	240.0	8	94.1
10-19	16	111.9	4	51.9
20-29	22	94.8	3	38.9
30-39	9	70.3	3	60.0
40+	3	83.3	1	28.6

The principal differences in the incidence of psychoneurotic disorders were seen in the women aged between 20 and 29, and, so far as can be judged from the small numbers in the population surveyed, in those over 40. This is shown in Table VI.

TABLE VI.—*Differences in Rates of First Consultation With the General Practitioners by Women for Psychoneurotic Disorders Between Those Living in Flats and Those in Houses, by Age Group*

Age Group	Group A: Flats		Group B: Houses	
	No. of First Attendances	Rate per 1,000 in Age Group	No. of First Attendances	Rate per 1,000 in Age Group
20-29	24	103.4	3	38.9
30-39	8	62.5	3	60.0
40+	3	83.3	0	0

The conclusions to be drawn from these figures are that there was an increase in general morbidity in the families who lived in flats as compared with those who lived in houses, and that this increase was most pronounced in children under the age of 10, who had more respiratory disorders, in those women between the ages of 20 and 29, who had more respiratory and psychoneurotic disorders, and probably in those women aged 40 and over, who also had more psychoneurotic disorders.

The differences which were recorded over this period were not unusual ones, as the rates of surgery attendances and domiciliary visits during the 10 weeks were not unusually high or low for either of the groups concerned, so it seems reasonable to conclude that those families who lived in flats were not as healthy as those who lived in houses. The amount of ill-health in flats appeared to be considerable, but the degree less so. Though there was one death during the period—that of an infant living in a flat who succumbed to a fulminating virus pneumonia—if the degree of illness is judged by the number who had to be admitted to hospital this was proportionately the same in both groups (Table II).

Respiratory Infections

The classical reasons for an increased rate of respiratory infection—namely, overcrowding and poor ventilation—were not present by the accepted standards. These flats were of a good size, with two or three bedrooms, and centrally heated throughout, allowing free use of all the floor space in comfort; nevertheless, the floor space in modern flats usually approximates more closely to the minimum standards laid down for dwellings, bedrooms tend to be smaller than they are in houses, and the whole design is more compact than in a house, bringing the occupants into closer contact.

Apart from floor space, the main difference between a house and a flat is the ease of access to the open air in the

former, and this may well have been a major reason for the increased rate of respiratory infections among flat-dwellers. A child returning home from school to a house will probably go out to play in the garden, but one coming back to a flat tends to remain there. Though play areas were provided in the communal surrounds of the flats, and were used to some extent, one never saw as many children using the swings and slides even on a fine day, as might have been expected from the number of children in the neighbourhood. On the other hand, large numbers of children in the back gardens or playing on the communal lawn in front of houses were a far more usual sight. Mothers who live up several flights of stairs tend to use them as little as possible, and are naturally reluctant to let small children too far out of their sight, and the children themselves are often unwilling to stray too far from their mothers. A further indication that people tend to be less active and more confined when they live in a flat is the significantly higher rate of musculoskeletal disorders found during the period under review in the group living in houses.

If confinement to the flat is a factor in precipitating respiratory infections one would expect to find a higher incidence in those living above ground level than in those who were on the ground floor and therefore probably more likely to go out, and this was found to be the case, as is shown in Table VII.

TABLE VII.—*Incidence of First Attendance by the General Practitioners on Families Living in Flats for Respiratory Disorders, by Height of Residence*

Level of Flat	First Attendances for Respiratory Disorders	Population at that Level	Rate per 1,000 at that Level
Ground floor	68	351	193.7
First	71	49	203.4
Second	74	37	219.6
Third	31	126	246.0
Total	244	1,163	209.8

It will be seen that there was a small but steady increase in the incidence of respiratory disorders as the height of the flat increased, though the flats were of the same design and size on each floor. The smaller population living on the third floor is due to the fact that most of the blocks were only three storeys high.

Neuroses

Though few in number by comparison with respiratory ailments, the incidence of psychoneurotic disorders as judged by their first presentation to the general practitioners was nearly three times as high in women in their twenties who lived in flats as it was in those living in houses. The numbers recorded in both groups were probably lower than the true incidence, as an attendance was put into this category only when a firm diagnosis of psychoneurotic illness could be made. Many others which would probably fall into this category were recorded under the heading of "vague symptoms and no diagnosis," as this miscellaneous group included the occasions when a wife might come herself or even bring a child with some superficially trivial problem, just so that she could talk with a neutral person such as the doctor.

The degree of illness was not usually serious, and most of the cases could be and were treated by the general practitioners concerned, backed up by the health visitor. During the 10-week period five patients who lived in flats were referred to the psychiatrist, and three who lived in houses. There was one psychiatric admission to hospital, and this was of a woman who lived in a house. Nevertheless, these illnesses, however mild, are often prolonged and disabling, and tend to become recurrent. It was felt that those patients who presented with psychiatric symptoms were only the tip of the iceberg, and a high proportion of undisclosed and undiagnosed mental illness

probably went unnoticed, and that part of the overall increase in the incidence of disorders in other categories, particularly gynaecological disorders, reflected underlying tensions and anxieties.

The causes were probably many, but there is no doubt that monotony and boredom played a considerable part. The flats were well appointed and designed to save labour, and women occasionally complained to their doctors about this, saying that the housework took so little time that there was nothing left to do. Again, because shopping facilities were close at hand, even a daily expedition took little time. It was possible to take a bus to another and bigger shopping centre, but, as with going for walks locally, this activity soon palled, and all that was left was confinement within the flat and introspection. If there were children below school age in the family this confinement became even more necessary, as they had to be watched all day. There was no small garden into which they could be released in safety, and they themselves eventually provided another irritant in their mothers' lives.

The most striking contrast between life in flats and that in houses was the lack of communication between families living in flats compared with those in houses, and this was probably the principal cause of the isolation and loneliness of the wives in the flats. Apart from the discussions in the surgery when this was revealed, it was noticed by the doctors and by the health visitor in the daily round, when one could observe the contrast during domiciliary visits. It was not uncommon to find neighbours visiting and talking when one visited a house, and if a wife was ill in bed the door would often be opened by a neighbour who had come in to help. This was not nearly so frequent in the flats, where it was more usual to find a wife coping by herself, or whose husband had had to stay away from work to help.

This phenomenon of isolation has previously been described as occurring on new housing estates, as in Young and Willmott's (1962) families who moved from Bethnal Green, and arises from the destruction of the matrilocal family structure, where mothers and their married daughters living near each other communicate frequently and form an extended family which is interdependent and which constitutes a self-sufficient social unit. Why, though, should this affect people who live in flats more than those who live in houses? Perhaps because in houses the children, instead of helping to confine their mothers indoors as they do in a flat, form a link between the women by bringing their mothers together when they play in their gregarious bands around the front doors. Stepping outside the front door or talking over the back-garden fence requires much less effort than climbing the stairs of a block of flats, and the gardens are neutral territory which do not involve the positive social act of going to call on someone in a flat. Thus the initial shyness of a woman who may be susceptible to mental illness may be broken and the illness prevented.

Some support for this can be found if the incidence of psychoneurosis is examined in relation to the height of the flat, and in Table VIII the women who made first attendances on the general practitioners at which a diagnosis of psychoneurotic disorder was made are divided according to the height

of the flat in which they lived. This shows that the incidence of psychoneuroses in women was twice as high if they lived on the top floor as it was in those who lived on the ground floor, and that there was a steady increase in incidence as the height of the residence increased.

Further support for this explanation of the situation is found in the observation that women in their thirties did not seem to suffer from mental illness if they lived in a flat any more than if they lived in a house. These were the women whose children were at school and therefore did not confine them to the flat. They were also those who went out to work, as many did in full- or part-time jobs in shops and offices, thus making social contacts and avoiding isolation.

The women aged 40 and over seemed to suffer because they were less tolerant of a new situation than the younger wives. They had been used to living in houses previously, and many could not adapt themselves to flat life.

With women of all ages it may have been that this increase in morbidity and intolerance of flat life would not have occurred but for the fact that their basic cultural pattern had already been disturbed, and that living in flats in a community which had a more acceptable social pattern would have been better tolerated.

Discussion

The health of this community might be expected to be relatively good, as they had committed themselves to a turbulent domestic life where they were expected to travel around the United Kingdom and overseas as the men's occupation required, and there was the possibility of an element of selection in this respect. They were, however, subject to stresses and lived under conditions which were very similar to those found in a new housing estate in England. The break in their family links was voluntary in that all the men had chosen the armed Services as their career, accepting the disturbance of family ties that must follow. This makes direct comparison with the health of a population on a new housing estate or in a new town in England difficult, but the increase in morbidity of the families who lived in flats does indicate that a health problem can exist and the nature of the illnesses which such a situation may precipitate.

With the two most important types of illness which arose in these families—namely, respiratory infections and psychoneuroses—though they may not be regarded as very serious at the time, they may both lead eventually to chronic disability. Recurrent respiratory infections in children will cause underlying structural damage and eventually chronic bronchitis and bronchiectasis, a pathological pattern already notorious in England. Even mild neurotic illnesses tend to be prolonged and difficult to treat successfully, and are apt to recur. The pattern of social withdrawal and confinement to the dwelling of young mothers and children is one which invites chronic ill-health, and is against all the tenets of good hygiene.

The problems of living in flats are recognized by some of the planners of new housing, but it is important that they, and more particularly doctors who work in general practice and in the field of public health, should attempt to evaluate them on a wider scale than has yet been done, and that public and private authorities who are responsible for building homes should be made aware of them. In particular, more research is needed into the problems of morbidity of families who have had a double social disturbance by being removed from their places of origin and also placed in a flat.

Summary

Two groups of families of members of the armed Services stationed in Germany were compared, one group living in

TABLE VIII.—Incidence of First Attendance by the General Practitioners on Females Aged 15 and Over for Psychoneurotic Disorders, by Height of Flat

Level of Flat	Females Aged 15 and Over		
	First Attendances for Psychoneurotic Disorders	Population	Rate per 1,000
Ground floor	8	127	63.0
First "	8	120	66.7
Second "	14	128	109.4
Third "	7	55	127.3
Total	37	430	86.0

flats and the other in houses. It was found that the morbidity of those families who lived in flats was 57% greater than of those who lived in houses, and that the greatest differences were seen in the incidence of respiratory infections in young women and children, and of psychoneurotic disorders in women.

The reasons for the differences in respiratory infections were felt to be the relatively small space available in a flat compared with that in a house, and confinement of the family within the flat. This confinement, and the resulting social isolation, were thought to be the reasons for the increase in psychoneuroses in the women.

The families concerned had had a double social disturbance in that their family ties had been severed and they were also subject to the restricting environment of life in a flat, and it is suggested that in view of the large number of flats which are being built, and the tendency towards family mobility,

further investigation is needed into the effects of flat life on health.

I am grateful to the Director, General of Medical Services, Royal Air Force, for permission to publish this paper.

Effect of Gastrin II on Gastric Emptying and Secretion During a Test Meal

J. N. HUNT,* M.D., D.S.C., M.R.C.P.; N. RAMSBOTTOM,* M.B., B.S.

Brit. med. J., 1967, 4, 386-390

Hypersecretion of gastrin by an islet cell tumour of the pancreas is believed to be the cause of the Zollinger-Ellison syndrome (Zollinger and Ellison, 1955; Gregory, Tracy, French, and Sircus, 1960). Patients with this condition have extreme gastric hypersecretion and peptic ulceration. In one case described by Lawrie, Williamson, and Hunt (1962) there was also very rapid gastric emptying. This feature seemed to be explained when Smith and Hogg (1966) found that injected gastrin stimulated gastric motility as judged by measurements of intraluminal pressure. We therefore expected that an increase in the rate of gastric emptying would result from intravenous infusion of gastrin, but this was not so.

Procedure

The plan of the experiments is set out in Fig. 1. Three test meals were given in succession with a 10-minute interval between them. For the 10 minutes before and during the second meal a continuous intravenous infusion of gastrin was given. The stomach was washed out with 250 ml. of water before each meal in order to remove any residual secretion. Each of the three tests of gastric emptying, which lasted 10 minutes, was separated from the subsequent test by 10 minutes. The meals consisted of 750 ml. of 100 mN sodium citrate containing 30 ml. of a saturated solution of phenol red per litre as marker. They were instilled down a tube into the stomach in about 75 seconds. This meal was chosen because it empties very rapidly; also it is buffered by the presence of the citrate ion, so minimizing the possible slowing action of secreted acid. Immediately after recovery of the first meal injection of gastrin into the running intravenous infusion was begun and continued for 20 minutes. Hog gastrin II was used in doses ranging from 0.125 to 3 μ g./min.

The recovered gastric contents were analysed according to the method of Hunt (1954, 1959). The volumes of original meal present in the recoveries were calculated as the product of the volume recovered and the ratio of its phenol red con-

centration to that of the original meal. The parietal secretion was calculated and expressed as millilitres of 160 mN HCl. The two of us, 75-kg. men aged 50 and 27, were the subjects for this investigation.

Results

The meal which was given during the infusion of gastrin left the stomach more slowly than the preceding or the succeeding meal. The minimal effective dose of gastrin in subject N.R.

FIG. 1.—Plan of experiment.

was 0.5 μ g./min. (Fig. 2) and, in subject J.H. 2 μ g./min. (Fig. 3). In both subjects the threshold for stimulating secretion of acid in the second meal was less than that required to slow emptying—0.125 μ g. in N.R. and 0.5 μ g. in J.H. (Figs. 4 and 5). With most doses the slowing of emptying had worn off in the 10 minutes between stopping the infusion of gastrin and giving the third meal. On the other hand, with the larger doses, 0.75 μ g. in N.R. and 2 μ g. in J.H., the secretion of acid in response to the third meal was greater than that in response to the second, though there was no injection of gastrin during the third meal.

Discussion

It was believed that the hormones of the alimentary tract—for example, cholecystokinin, pancreozymin, and gastrin—had specific actions on their target organs. Originally gastrin was thought to act only on the parietal cell (Uvnäs, 1948), but more recently it has also been found to affect pepsin production and the secretion of protein by the pancreas (Emås and Grossman, 1967; Preshaw and Grossman, 1965). There is now evidence that gastrin also increases motility of the alimentary tract (Gregory and Tracy, 1964; Smith and Hogg, 1966). Because of the rapid gastric emptying seen in a patient with the Zollinger-Ellison syndrome, we expected infused gastrin to increase the rate of emptying. However, 0.5 $\mu\text{g./min.}$ (0.007 $\mu\text{g./kg./min.}$) in N. R. and 2 $\mu\text{g./min.}$ (0.03 $\mu\text{g./kg./min.}$) in J. H. slowed the emptying of the stomach. These doses were submaximal for the secretion of acid, since the next higher dose gave a greater secretion of acid and a greater slowing of gastric emptying.

Acid in test meals slows gastric emptying (Shay and Gershon-Cohen, 1934 ; Hunt and Pathak, 1960). However, the slowing of gastric emptying by gastrin was not caused in this way. For example, 0.75 μ g. of gastrin per minute in N.R. increased the recovery of test meal from 200 to 600 ml. The volume of parietal component secreted during this second meal was 28 ml., and the titratable acid was 5.6 mEq/l. of gastric contents. For the third meal the recovery of test meal was only 100 ml., yet the secretion of parietal component was 50 ml. and the titratable acidity of the gastric contents was 16 mEq/l. The secretion of parietal component before gastrin was given was 14 ml., with a titratable acidity of the gastric contents of 3.6 mEq/l. There was in this experiment, and in most of the others, a clear dissociation between gastric emptying and the titratable acidity of the gastric contents. Thus the slowing of emptying by gastrin was not caused by increased acidity of the gastric contents.

Gastrin and its pentapeptide analogue (I.C.I. 50.123) were found to increase the motility of the alimentary tract as indicated by changes in intraluminal pressure (Gregory and Tracy, 1964; Smith and Hogg, 1966). The slowing of gastric emptying by gastrin may result from a general increase in the tone of the gut. When this happens those parts of the alimentary tract with the smaller diameter are at a mechanical

advantage because of the operation of the law of Laplace (Brody and Quigley, 1948). Thus contraction of the duodenum may prevent the stomach from emptying. This appears to be the mechanism by which morphine slows gastric emptying (Folley and Osler-Abbott, 1942).

The difference between the rapid evolution of the maximal slowing of emptying and the slow approach to maximal secretion is worth comment. Presumably the motor response to gastrin depends on the plasma concentration. The delay in secretory response to gastrin may be analogous to the delay in response to aldosterone, which delay is currently ascribed to the induction of an enzyme (Sharp and Leaf, 1966). This would fit in with the work of Blair (personal communication), who found that, with a single intravenous dose of gastrin, by the time the peak of acid secretion was reached the concentration of gastrin in the plasma was only 3% of the initial level.

Summary

The effect of gastrin II on gastric emptying and secretion was examined in two men. The rate of gastric emptying was slowed in proportion to the dose given. The increased rate of gastric secretion of acid long outlasted the slowing of gastric emptying.

We should like to thank Professor R. A. Gregory, who kindly supplied us with the gastrin for this experiment.

Which Stethoscope?

C. S. HAMPTON,*† M.B., CH.B.; A. CHALONER,*‡ M.B., CH.B.

Brit. med. J., 1967, 4, 388-390

The choice of a stethoscope is largely irrational. The newly fledged medical student is either likely to follow his professor's choice or buy the latest slim-line model. However, it would seem that an instrument which is an extension of the clinician's sensory system should be chosen on some rational basis.

Previous papers on this subject have described tests of stethoscope components rather than complete instruments. This would seem to be of limited value, as the acoustic properties of the complete instrument need bear no direct relation to that of its components.

Recently several stethoscopes have been manufactured which have tended to be lighter, more compact, more pleasing in

FIG. 1.—Guy's chestpiece used as "basic."

appearance, and more expensive. In this paper we have attempted to compare the performance of the newer stethoscopes with older and cheaper models.

Materials

The materials used in this experiment were:

(1) Peter's SPD5 audiometer connected to a vibrator unit (bone conduction).

TABLE I.—*Stethoscope Dimensions*

Stethoscope	Tubing Length and Internal Diameter	Binaural Length and Internal Diameter	Chestpiece Area of Skin Covered (sq. cm.)	Internal Volume (ml.)	Price £ s. d.

{ Bell	3.0 mm.	3.0 mm.			
{ Diaphragm					
Wooden monaural	17 cm. Diameter variable		2.3		

The internal volumes were measured by filling the stethoscopes with mercury and measuring the volume of the mercury with a burette.

* Tubing shorter than original length.

(2) Normal human chest.

(3) *Stethoscopes*.—The stethoscope chosen as "basic" had the Guy's rubber-ended chestpiece as shown in Fig. 1. Compared with this basic were: (i) Sprague (Reiger) Bowles bell and diaphragm; (ii) Leatham large and small bells and diaphragm; (iii) Littmann bell and diaphragm; (iv) Allen bell and diaphragm; and (v) wooden monaural stethoscope. Dimensions and prices of these stethoscopes are given in Table I.

The auscultator was the same observer throughout.

Method

A Peter's SPD5 audiometer with a bone conduction vibrator was used as a source of sound. The audiometer vibrator was placed in the suprasternal notch of a live human subject. The auscultator listened for the sound by holding the chestpiece of the stethoscope on a point 7.5 cm. from the anterior midline in the fifth right intercostal space of the subject. With the lowest frequencies the position of the chestpiece was in the right first interspace 5 cm. from the midline, as in the more caudal position no signal was received. This arrangement allowed the emitted vibration to be conducted through the chest of the subject without either the subject being aware of the vibration or the auscultator receiving any sound by direct air conduction.

At each session, lasting about an hour, one frequency only was considered; the whole range of stethoscope chestpieces was tested for this one frequency. Output and frequency controls of the audiometer were recalibrated at the beginning of each session. Tones interrupted three times per second were used to facilitate interpretation; the audiometer was operated by the auscultator. Thirteen frequencies spaced at approximately equal intervals along the logarithmic scale between 0 and 1,000 c/s were chosen, as the usual auscultatory sounds lie within this range (Rappaport and Sprague, 1941).

On the Peter's SPD5 audiometer the only frequencies already calibrated between 0 and 1,000 c/s were 250, 750, and 1,000 c/s. The other frequencies chosen arbitrarily for this experiment were subsequently calibrated by means of the beat frequency technique. The apparatus used was a radiometer beat frequency oscillator HO 32 connected to a 10-in. (25-cm.) loudspeaker. A stethoscope was used to compare the frequencies emitted by the audiometer vibrator and the loudspeaker, the vibrator being placed between the stethoscope chestpiece and the loudspeaker. It was found by this technique that the 250 c/s reading on the audiometer was in fact 240 c/s. The other frequencies used are given with the results in Table II.

Ten readings for the basic stethoscope were made; the lowest intensity which could be interpreted was read in decibels from the audiometer scale—this being taken as the threshold. The same chest position was used and comparison was made with the various stethoscopes, there being 10 readings for each chestpiece bell or diaphragm. Twice during the session a further 10 basic readings were taken, making a total of 30 basic readings

* Demonstrators, Department of Physiology, St. Andrews University, St. Andrews, Fife.

† Late Medical Registrar, the County Hospital, Dorchester, Dorset. Present address: Renal Unit, Leeds General Infirmary, Leeds 1.

‡ Now Medical Officer (Research), R.A.F. Institute of Aviation Medicine, Farnborough, Hants.

for each frequency tested. The procedure was followed for each of the 13 frequencies.

Results

It was found that on deep inspiration the threshold was raised by about 5 db; however, during our experiment the subject was at rest and breathing was shallow. Under these conditions the threshold did not vary appreciably with respiration.

Accurate positioning of the chestpiece on the chest wall was essential for consistent thresholds at the lower frequencies.

Thresholds varied by up to 5 db with changing pressure of application by the auscultator on the chestpiece. The threshold values in this paper were obtained by using the optimal pressure for each stethoscope chestpiece at each frequency.

The lowest frequency measured by our technique was 73 c/s, owing to the low output of the bone conduction vibrator at lower frequencies.

The auscultator noted that the subjective quality of sounds heard via different stethoscopes varied.

The results are set out in Table II. Each figure in this Table is the mean of 10 threshold determinations, 30 in the case of the basic stethoscope. Column C gives the standard deviation of 30 basic thresholds; from these figures some idea of the consistency of the thresholds may be obtained. Application of the method of analysis of variance and Student's *t* test yielded the figures for column D.

Statistical significance of the results can be assessed by adding or subtracting the figure in column D from the basic results shown in column B. These limits must then be compared with the results shown under each stethoscope heading at the same frequency. Subsequent columns give figures which are the mean of 10 thresholds for the stethoscopes tested. The thresholds were measured repeatedly and statistical methods were applied in an attempt to compensate for threshold inconsistencies.

Fig. 2 summarizes the data in Table II. High and low frequencies were considered separately because of the oft-quoted axiom that low frequencies are best heard with bells and high frequencies with diaphragms.

Discussion

Dawson (1964) states that heart and chest sounds fall into the following frequency ranges:

Low heart sounds (presystolic and some systolic murmurs; basal and mitral diastolic murmurs; auricular and first, second, and third heart sounds; gallop rhythms) ...	20-115 c/s
Medium and high heart sounds (systolic and diastolic murmurs) ...	200-660 c/s
Pericardial rubs ...	140-660 c/s
Amphoric breathing ...	240-660 c/s
Bronchial breathing ...	240-1,000 c/s
Crepitations ...	750 c/s upwards
Vesicular breathing ...	150-1,000 c/s
Breath sounds heard in trachea, bronchi, bronchioles ...	800 c/s upwards
Foetal heart sounds ...	16 c/s upwards

The figures given for the required variation from basic mean at the 5% level of significance were obtained by using the method of analysis of variance and Student's *t* test. Each figure is the mean of 10 readings (30 in the case of the basic stethoscope).

S.D. = Standard deviation. * Significantly better than basic. † Not significantly different from basic. ‡ Significantly worse than basic.

FIG. 2—Summary of data given in Table II.

It would appear that any frequency falling between 20 and 1,000 c/s is of relevance to some clinical situation.

The stethoscopes used in this experiment were chosen as being most representative of those in general use, the exception being, of course, the wooden monaural.

An initial attempt to reproduce the experimental conditions of Rappaport and Sprague (1941) was unsuccessful, as it proved impossible to obtain an effective soundproof seal between the chest wall and a loudspeaker baffle.

Some previously enunciated principles of stethoscope design may now be examined in the light of our results.

(1) "It is apparent that the larger the area of the stethoscope piece in contact with the chest, the greater the amount of sound collected" (Macfarlan, 1938). The Leatham big bell has a performance somewhat inferior to that of the little bell; the skin area enclosed by the Sprague-Bowles bell is greater than that of the basic stethoscope, yet the performance of the Sprague-Bowles bell is inferior, though the two stethoscopes have similar tubing and binaural dimensions.

(2) A good stethoscope needs both a bell and a diaphragm chestpiece (B.M.J., 1962). The Sprague-Bowles diaphragm is superior to the bell in both the higher and lower frequencies. The Littmann diaphragm performs better than the bell in the lower frequencies; the converse applies at the higher frequencies. Both the Allen and the Leatham bell seem to be superior to their respective diaphragms at both higher and lower frequencies.

(3) A stethoscope should have a small internal volume (Barss *et al.*, 1926; Rappaport and Sprague, 1951). In general our results seem to support this principle. The Leatham and the Allen both use small-bore tubing (diameter 0.3 cm.) and have small internal volumes.

In general these results differ from those of Barss *et al.*, (1926) and Rappaport and Sprague (1941, 1951). Barss *et al.* concluded that increasing the area of the chestpiece leads to greater efficiency. Their conclusions were based on an experiment involving the passage of sound from a source, through air, to the chestpiece; these conditions are very different from

those obtaining in the clinical use of the stethoscope. Rappaport and Sprague compared stethoscope components rather than complete stethoscopes. The acoustic properties of any component are very different from those of a stethoscope incorporating that component.

It is suggested that in stethoscope design most of the previously accepted principles should be ignored and an empirical approach should be used. Stethoscopes of small internal volume might be modified step by step, discarding modifications leading to an inferior performance and incorporating those leading to improved performances.

The conditions of testing should correspond as closely as possible to those in clinical use.

Summary

A comparison has been made of the efficiency of various stethoscopes in common clinical use by simulating natural conditions as far as possible. Of the stethoscopes tested by this method the Leatham little bell and the Allen bell gave the best overall performances. The current prices in the U.K. of the various stethoscopes are listed. It is suggested that an empirical approach to stethoscope design is adopted, though, in general, stethoscopes with small internal volume and small endpiece skin contact gave the better performances.

We would like to thank Dr. J. H. Taylor, who originally suggested that we should attempt a *Which?* report on stethoscopes, and Professor A. E. Ritchie for his help and advice. Mr. P. D. L. Constable gave invaluable help with the statistics.

Location of Placenta by Means of a Colour Autoscan Technique

W. THOMPSON,* M.B., B.Sc., M.R.C.O.G.; T. K. BELL,† B.Sc., A.Inst.P.; J. H. M. PINKERTON,* M.D., F.R.C.O.G.

Brit. med. J., 1967, 4, 390-391

Location of the placenta by radioactive scanning techniques has considerable advantages over existing x-ray methods and is being used with increasing frequency (Hibbard, 1966). When tracer doses of isotopes tagged to human albumin are employed the radiation risk to the foetus is greatly reduced (McGee and Duron, 1960). In 1966, at the Royal Victoria Hospital, Belfast, a colour autoscan apparatus became available that could be adopted for use in placentography. This paper describes the use of this apparatus and the results so far obtained in 62 cases.

Method and Equipment

Lugol's iodine solution, 0.3 ml. three times daily for 24 hours before and seven days after the test, was given to block the maternal and foetal thyroid (Cavanagh *et al.*, 1961).

Human serum albumin labelled with ¹³¹I, obtained from the Radiochemical Centre, Amersham, was diluted in saline and

5 microcuries administered intravenously to each patient. Five to 10 minutes were allowed for the radioactive compound to mix throughout the vascular department. The patient was then placed supine on the couch of a total body scanner (Isotope Developments Ltd., Reading) beneath a fixed scintillation counter in axial alignment with another similar counter below the couch. Each counter contained a 3-in. (7.5-cm.) diameter sodium iodide crystal in a 3-in. diameter lead collimator. The couch was mechanically moved backwards and forwards between the counters along parallel lines separated by a distance of 1 cm. until the whole abdominal area was scanned.

The radiations detected by each counter are converted to electrical pulses, added together, and operate a striker and the six-colour ribbon beneath it. Distribution of the radioactivity is displayed on a sheet of paper in the form of coloured dashes, indicating regions of high and low concentrations. This double counter system gives higher counting rates, better distinction, and a shorter operating-time—approximately 20 minutes—as compared with the single counter placed above the patient used in earlier work in this series.

* Department of Gynaecology, the Queen's University, Belfast.

† Department of Medical Physics, Royal Victoria Hospital, Belfast.

At the end of the scan the individual counting rates from each detector viewing the "hot" region indicate whether the placenta was anterior or posterior.

Results

The indications for placentography were a suspicion of placenta praevia in 58 patients who presented with antepartum haemorrhage (52) or a persistent unstable lie at 37 weeks (6) (see Table), and the need to define the placenta before amniocentesis in four. The usual gestation period at which the test was performed was 32–33 weeks, but satisfactory results were obtained as early as 30 weeks. In four patients placenta praevia diagnosed on scanning was not confirmed clinically. These false-positive results were due mainly to overcautious assessment of the scans early in the series, and with experience it has been possible to increase the accuracy of prediction. Of 42 patients with antepartum haemorrhage 32 were allowed home for intervals of two to six weeks after placentography had indicated that the placenta was in the upper uterine segment; no foetal loss resulted.

Summary of Results

Placental Site	Autoscan Report	Correct at Delivery	Accuracy
Upper uterine segment	42	42	100%
Lower " " "	16	12*	75%
Total	58	54	93%

* Four false-positive results.

Discussion

Clinical Applications.—The accuracy of the method described is 93%, and is comparable to that of other reported isotope techniques; its main clinical value is the exclusion of placenta praevia before allowing the patient home for part or all of the remainder of the antenatal period, and it is important in this connexion to note that in no patient was a placenta praevia missed. In this way we calculate that the equivalent of three out of 100 hospital beds a year are released for other purposes. No attempt was made to estimate the degree of placenta praevia, as all cases carry the risk of further possible severe haemor-

rhage, and are therefore kept in hospital until after delivery. The other application of the procedure is before amniocentesis, when there is clinical evidence of an anteriorly placed placenta. Here the scan is useful in the selection of a suitable puncture site.

Choice of Isotope.—Albumin tagged with ^{131}I was chosen as the most suitable tracer material, because it has been successfully used elsewhere for placental location (Weinberg *et al.*, 1957; Heagy and Swartz, 1961; Durfee and Howieson, 1962), its biological characteristics are fully known, its production is reliable, it is relatively cheap, and it is readily obtained commercially. Isotopes such as ^{132}I and technetium 99m have the advantage of a much shorter half-life, so that larger quantities of radioactive material can be used, resulting in higher counting rates and better discrimination. If, however, the facilities required for routine production of albumin tagged with these isotopes are not available ^{131}I albumin has been shown to give satisfactory results.

Summary

A technique of isotope placental location is described which uses ^{131}I and a colour autoscan apparatus. The use of a two-collimator modification has been found to increase the definition of this method, so that the readily available albumin-tagged ^{131}I gave satisfactory results.

The accuracy of the method was 93%; no placenta praevia remained undetected.

We are indebted to the consultant staff of the Royal Maternity Hospital, Belfast, for permitting us to include their patients in this study. Our thanks are also due to Dr. R. Ferguson and Dr. W. B. Sproule for their help.

Adrenocorticotrophic Action of Long-acting Tetracosactrin Compared with Corticotrophin-gel

G. M. BESSER,* M.D., B.SC., M.R.C.P.; P. W. P. BUTLER,* M.B., B.S., M.R.C.P.

Brit. med. J., 1967, **4**, 391–394

Tetracosactrin (β^{1-24} corticotrophin, Synacthen) is a synthetic polypeptide containing the first 24 amino-acids found in naturally occurring corticotrophin (A.C.T.H.). It has a high degree of corticotrophic activity (Landon *et al.*, 1964) and is used to test adrenocortical responsiveness (Wood *et al.*, 1965). However, since its action lasts only three to four hours after an intramuscular dose (Landon *et al.*, 1964), unmodified tetracosactrin can have little place in therapy. A long-acting version of this compound might offer practical advantages over naturally occurring corticotrophin, particularly in patients who develop hypersensitivity reactions or antibodies to natural corticotrophin, since its amino-acid sequence is identical with that of

the active portion of human corticotrophin and the preparation does not contain any animal contamination. Tetracosactrin has now been modified by adsorption on to an inorganic zinc complex to prolong its action. This paper reports a comparison of its adrenocorticotrophic properties and length of action compared with corticotrophin-gel of animal origin in normal subjects and in patients previously treated with oral corticosteroids or corticotrophin.

Methods and Subjects

Subjects.—All subjects were volunteers without evidence of endocrine, renal, or liver disease. There were 18 non-steroid-treated subjects, of whom eight were ambulant medical staff,

* Medical Professorial Unit, St. Bartholomew's Hospital, London E.C.1.
 † Department of Anaesthesia, St. Bartholomew's Hospital, London E.C.1.

four were inpatients who did not require corticosteroid therapy, and six were patients in whom corticosteroid therapy was indicated by the severity of their underlying disease. In the steroid-treated group there were six patients treated with prednisolone for more than three months (range 4 to 12 months) and six treated for less than three months (1 to 10 weeks). The dose varied from 10 to 60 mg./day. The six corticotrophin-treated subjects had received 40–80 units of corticotrophin-gel daily for one to three weeks, and the injections were stopped 48 hours before the test.

Trial Design and Analysis.—There were three treatments—1 and 2 mg. of depot-tetracosactrin, and 80 units of corticotrophin-gel (Armour) of a single batch number (MB 0802). The treatments were given intramuscularly at 72-hour intervals between 9 and 10 a.m. and the order of administration was randomized and balanced among the subjects by means of orthogonal latin square designs. Plasma cortisol estimations were performed at 0, 2, 4, 8, 12, 24, 32, 48, and 72 hours after drug administration. The changes in plasma cortisol were initially analysed by the method of analysis of variance (Snedecor, 1956), and the differences between the means at each time were tested by Hartley's (1955) modification of Student's *t* test.

Plasma Cortisol Assay.—Plasma 11-hydroxycorticosteroids were measured by the fluorimetric method of Mattingly (1962). This measures principally cortisol (hydrocortisone), as well as small amounts of circulating corticosterone and some other unknown fluorescent substances. The combination is referred to as "plasma cortisol" in this paper.

Results

Initially results from the patients requiring corticosteroid therapy were analysed separately from those from the other normal subjects, as they were somewhat stressed and might have given different responses. Their results were subsequently combined, since there were no significant differences between the responses of the two subgroups and their variances were homogeneous. This whole group is referred to as "normal subjects." The two groups of corticosteroid-treated patients were also combined in the final analysis, as their responses and variances were not significantly different.

Normal Subjects (Fig. 1)

The mean plasma cortisol levels after the three treatments were not significantly different at 0, 2, and 4 hours, rising to over three times the resting concentration during this time. After 80 units of corticotrophin-gel the mean level rose further to a maximum of 69 $\mu\text{g./100 ml.}$ at eight hours, and then fell off rapidly to reach basal levels by 24 hours. After 1 mg. of depot-tetracosactrin the maximum mean plasma cortisol

occurred at four hours and was then 6 $\mu\text{g./100 ml.}$ less than the maximum after 80 units of corticotrophin-gel, but this difference was not significant. Compared with the response to the gel, the mean concentration fell more slowly after the 1-mg. dose and reached basal values at between 32 and 48

FIG. 1.—Mean plasma cortisol concentrations in 18 normal subjects after 80 units of corticotrophin-gel and 1 and 2 mg. of depot-tetracosactrin.

hours. The cortisol concentrations were significantly higher after 1 mg. than after the gel at 24 and 32 hours (see Table). After 2 mg. the maximum level was greater than after the gel or 1 mg. and remained higher from 4 to 48 hours, by which time it had just reached basal levels (23 $\mu\text{g./100 ml.}$). The differences from the levels after the gel were significant at 12, 24, and 32 hours and from the 1 mg. dose at 8, 12, 24, and 32 hours (see Table).

Corticosteroid-treated Patients (Fig. 2)

The general pattern of effects was similar in this group. However, the maximum plasma cortisol levels achieved were virtually the same on all three treatments and were about 30 $\mu\text{g./100 ml.}$ (40%) lower than in the normal subjects. Since these subjects' adrenal cortices were to a greater or less extent suppressed by the prednisolone treatment, the starting levels were low, but all three treatments provided a potent stimulus to the suppressed glands. In only 2 of the 12 subjects did the first treatment fail to raise the plasma cortisol above 25 $\mu\text{g./100 ml.}$, and in these this level was achieved after the second treatment in one and after the third in the other. The mean plasma cortisol concentration after the 80 units of corticotrophin-gel at 24 hours (27.5 $\mu\text{g./100 ml.}$) was only just above the upper limit for the normal range at 9 a.m. (6–26 $\mu\text{g./100 ml.}$), whereas after the 1-mg. dose of the depot-tetra-

cosactrin it did not fall to this level until 32 hours, and after the 2-mg. dose until 48 hours. However, the concentrations after corticotrophin-gel and the 1-mg. dose were not signifi-

FIG. 2.—Mean plasma cortisol concentrations in 12 corticosteroid-treated patients after 80 units corticotrophin-gel and 1 and 2 mg. depot-tetracosactrin.

cantly different at any time, though they were significantly greater after the 2-mg. dose compared with the gel at 24, 32, and 48 hours, and compared with the 1-mg. dose at 32 and 48 hours (see Table).

Corticotrophin-treated Patients (Fig. 3)

In these six patients the pattern of results was similar to that of the normal subjects except that the maximum levels of cortisol achieved were some 10 µg./100 ml. higher. In this small group the effect of the 1-mg. dose appeared to fall off more quickly than in the other groups, reaching 26 µg./100 ml. at 24 hours.

FIG. 3.—Mean plasma cortisol concentrations in six corticotrophin-treated patients after 80 units corticotrophin-gel and 1 and 2 mg. depot-tetracosactrin.

Clinical Features

The depot-tetracosactrin is an aqueous suspension of 1 mg. of powder in 1 ml. and was simple to give, unlike the corticotrophin-gel, which was viscous and required preliminary warming. Thirteen out of 36 subjects complained of local discomfort after the depot-tetracosactrin, particularly when this was given into the deltoid muscle rather than into the thigh or buttock. Of these subjects, three also had discomfort after the gel.

Though not specifically investigated, it was apparent that in those subjects with asthma and rheumatoid arthritis given the depot-tetracosactrin for therapy symptoms were relieved within two to three hours and the clinical effect of 1 mg. lasted about 32 hours.

Discussion

The depot-tetracosactrin powerfully stimulated the adrenal cortex under normal conditions and also when suppressed by exogenous corticosteroids or stimulated by a previous course of corticotrophin. Since there were no differences between the 1-mg. dose, the 2-mg. dose, and the 80 units of corticotrophin-gel over the first four hours, it may be presumed that the gland was maximally stimulated over this time by each treatment. In terms of the maximum plasma cortisol concentration achieved, 1 mg. of the new drug was not significantly different from 80 units of corticotrophin-gel. The depot-tetracosactrin, however, maintained the plasma cortisol level for longer, and it may be concluded that to maintain a continuously elevated plasma cortisol 1 mg. of the synthetic agent need be given only once daily while the corticotrophin-gel in this dose must be given twice daily. Since the cortisol concentrations after 2 mg. were considerably, and significantly, higher than after 1 mg. up to 32 hours, alternate daily administration might be sufficient at this dose.

It is established that A.C.T.H. of animal origin may produce severe and sometimes fatal hypersensitivity reactions (Wilson, 1951; Hill and Swinburn, 1954; Inderbitzin, 1954; Pearson, 1959; Rajka, 1961; Forssman *et al.*, 1963; Rosenblum and Rosenblum, 1964), though this must be a rare event with modern purified preparations. Jenny *et al.* (1963), Landon *et al.* (1964), and El-Shaboury (1965) challenged known corticotrophin-hypersensitive patients with the short-acting, unmodified tetracosactrin without producing hypersensitivity reactions, yet there was an adequate adrenocortical response in each case. However, the action of unmodified tetracosactrin is too short for practical therapy. The depot-preparation has a useful time course of action of 32 to 48 hours, and it is probable that at least a proportion of natural corticotrophin-hypersensitive patients could be treated with it.

Since stress-induced growth hormone release is inhibited by oral corticosteroids but not by corticotrophin (Frantz and Rabkin, 1964; Hartog *et al.*, 1964; Friedman and Stimmeler, 1966), corticotrophin therapy may be indicated rather than oral corticosteroids in children; there is evidence that "steroid-stunting" is less likely to occur (Friedman and Strang, 1966; Friedman and Greenwood, 1967). Similarly, A.C.T.H. release in response to stress is less likely to be suppressed after corticotrophin therapy than after oral corticosteroids (Savage *et al.*, 1962; Friedman and Greenwood, 1967). A complicating factor is the development of antibodies to the species-specific portion of the corticotrophin molecule in a high proportion of patients (Friedman and Greenwood, 1967) and sometimes acquired resistance to its adrenocorticotrophic action may develop (West, 1960, 1962). It is possible that corticotrophin of animal origin is more antigenic in man than the short-chain synthetic preparation containing the first 24 amino-acids of human corticotrophin in their natural sequence. The availability of a depot preparation of this synthetic tetracosactrin allows its antigenic potency to be tested in man, since it can be administered therapeutically on a long-term basis.

Bioassay initially showed that 1 mg. of tetracosactrin was equivalent to 106 units of animal corticotrophin (Schuler *et al.*, 1963). This study has suggested that the modified depot preparation of this polypeptide is somewhat less potent, 1 mg. being approximately equal to 80 units of corticotrophin.

Summary

The adrenocorticotrophic action of a long-acting version of the synthetic polypeptide tetracosactrin has been compared in two doses (1 and 2 mg.) with 80 units of a gelatin preparation of natural corticotrophin in 18 normal subjects, 12 corticosteroid-treated patients, and six corticotrophin-treated patients over 72 hours. In terms of the mean maximum plasma cortisol

concentrations attained 1 mg. of depot-tetracosactrin was approximately equivalent to 80 units of corticotrophin-gel. Mean plasma cortisol levels had returned to normal by 24 hours after the corticotrophin-gel, and by 48 hours after both doses of the depot tetracosactrin. To maintain a continuously elevated plasma cortisol corticotrophin-gel in this dose must be given twice daily and 1 mg. of the depot-tetracosactrin once daily; after 2 mg. alternate daily administration might be sufficient. All three preparations gave maximal adrenal cortical stimulation over the first four hours. The depot-tetracosactrin was simpler to give than the corticotrophin-gel. Local discomfort was more common after the synthetic preparation.

We are grateful to Professor E. F. Scowen and Dr. P. V. Cole for their interest and to the physicians of St. Bartholomew's Hospital and St. Leonard's Hospital for permission to study patients under their care. CIBA Laboratories kindly provided the depot-tetracosactrin, which is at present available only for clinical trial. We are particularly indebted to Miss Catherine Duncan for the statistical analysis.

Simple Screening Test for Cushing's Syndrome

D. MATTINGLY,* M.B., M.R.C.P.; CHRISTINE TYLER,† B.SC., PH.D.

Brit. med. J., 1967, 4, 394-397

Cushing's syndrome is now generally recognized to be due to the prolonged excessive secretion of cortisol (hydrocortisone), and all of the main clinical features of this disorder have been accidentally reproduced at one time or another in patients on corticosteroid therapy. Gross cases may present no difficulty in diagnosis, but in recent years it has become apparent that these are in a minority, since adrenal hyperfunction is often present in patients with few signs and symptoms suggestive of classical Cushing's syndrome (Ross *et al.*, 1966). Obesity is almost invariably present, but is of little diagnostic value because of its high incidence in the population as a whole, particularly in women between the ages of 20 and 50 years, who are the most likely to be suffering from Cushing's syndrome. Nevertheless, obesity is of some help in drawing attention to the possibility of this disease, and the suspicion of adrenocortical overactivity may be reinforced if the obesity is of central distribution and accompanied by hypertension, menstrual irregularities, hirsutism, or diabetes mellitus.

Clinical acumen, however, is insufficient to establish the diagnosis of this disease, and confirmation depends on showing that cortisol production is in excess of normal. The most reliable means of doing this is to measure the cortisol secretion rate by isotope dilution (Cope and Black, 1958; Brooks *et al.*, 1963; Cope and Pearson, 1965; Ross *et al.*, 1966). This technique has proved invaluable in equivocal cases, but is too highly specialized for routine clinical use. The same objection applies to the estimation of urinary cortisol excretion by chromatography, another procedure which has high diagnostic value (Cope and Black, 1959; Brooks *et al.*, 1963; Rosner *et al.*, 1963). At present most laboratories are only equipped to estimate urinary 17-oxogenic steroids or 17-hydroxycorticoids.

It is now clear, however, that these levels often fall within the accepted normal range in patients with undoubted Cushing's syndrome, and so are an unreliable index of cortisol production in this disease. Indeed, Cope and Pearson (1965) have shown that there is no correlation between the cortisol secretion rate and 17-oxogenic steroid excretion over the normal range and the region just above it where so many of the equivocal values lie.

In order to recognize Cushing's syndrome in patients who are not yet grossly diseased, a test is needed the results of which more accurately reflect the cortisol secretion rate, and which is simple enough to be carried out routinely for screening purposes. In 1964 a simple fluorimetric method was described for estimating unconjugated 11-hydroxycorticoids in urine (Mattingly *et al.*, 1964). These urinary 11-hydroxycorticoid estimations showed a better correlation with the cortisol secretion rate over the required range than did the 17-oxogenic steroids. Elevated levels were found in a number of patients with Cushing's syndrome, and it was suggested that this method might be of value in screening patients for this disease. The present paper extends these observations to include 34 patients with Cushing's syndrome, and compares their urinary 11-hydroxycorticoid excretion with that of control subjects and patients with "simple" obesity.

Materials and Methods

The ages of the subjects ranged from 13 to 72 years. They were divided into three groups:

- (1) A control group consisting of 50 females and 59 males made up of normal subjects and of convalescent hospital patients. The latter were not acutely ill and were under no obvious stress at the

* Director, Postgraduate Medical Institute, University of Exeter.

† Research Assistant, Postgraduate Medical Institute, University of Exeter.

time of urine collection. Patients with endocrine, liver, or renal diseases were excluded.

(2) A group of 62 female and 13 male patients who were obviously obese but had no other manifestation of Cushing's syndrome.

(3) A group of 27 female and 7 male patients with Cushing's syndrome. The series consisted of 25 patients with adrenal hyperplasia, 4 with adrenal tumours, and 5 with adrenal hyperplasia associated with "non-endocrine" tumours. The diagnosis was confirmed independently in 20 cases by estimation of the cortisol secretion rate (Mattingly *et al.*, 1964) and by inspection of the adrenal glands at operation or necropsy in the remainder. In all cases plasma 11-hydroxycorticoid levels were measured by fluorimetry (Mattingly, 1962). The normal diurnal variation of these levels was absent or greatly reduced in all 34 patients, and in 33 cases the plasma 11-hydroxycorticoid levels and urinary corticosteroids failed to suppress normally during dexamethasone administration (Mattingly, 1963; Cope, 1966).

Urine Collections.—Collections of urine over 24-hour periods from normal subjects and outpatients were made with no interruption of their daily lives. In ward patients a normal ward routine was followed, but care was taken to ensure that the patients were not subjected to any stressful procedure during the collection period. Subjects were instructed to empty their bladders before defaecation to avoid losses at this time. Urine was collected in Winchester bottles without any added preservative. The bottles had been washed with either chromic acid or the detergent Decon 75 (Medical-Pharmaceutical Developments Ltd.). This latter substance, unlike most other detergents, does not fluoresce and so does not interfere with the steroid estimations (V. H. T. James, personal communication). Since it is more convenient to use than chromic acid it was used exclusively in the latter stages of the work. If the analyses were not undertaken immediately a 20-ml.

aliquot of the urine was deep-frozen within a few hours of the completion of collection.

Determination of 11-Hydroxycorticoids.—The fluorimetric method of Mattingly *et al.* (1964) was used throughout, using 2 ml. samples of urine. Latterly, the detergent Decon 75 was used to wash glassware in place of the less convenient chromic acid. In all cases the alkali wash consisted of 2 ml. of 1N sodium hydroxide. The fluorescence was read on a direct-reading fluorimeter (model 27A, Electronic Instruments Ltd.), with excitation at 430 m μ and emission at 540 m μ . The precision and accuracy of the method were good. The coefficient of variation over the normal range was 8%, and the mean recovery of added cortisol in amounts ranging from 0.1 to 5 μ g. was 97.2%. Results are expressed throughout in terms of cortisol.

Determination of 17-Oxogenic Steroids.—These were measured in the routine biochemistry laboratory by the method of Gibson and Norymberski (1954) or of Appleby *et al.* (1955). The same 24-hour urine samples were used as those for the determination of 11-hydroxycorticoids, but 17-oxogenic steroid estimations were not carried out on all of them.

Results

Control Group.—In 50 females between the ages of 14 and 67 the urinary excretion of 11-hydroxycorticoids ranged from 78 to 311 μ g./24 hours, with a mean of 174 ± 53 (S.D.) μ g./24 hours (Fig. 1). In 59 males between the ages of 17 and 70 years the figures were somewhat higher, and ranged from 108 to 396 μ g./24 hours, with a mean of 229 ± 66 (S.D.)

FIG. 1.—Levels of free 11-hydroxycorticoids in the urine of female subjects. Each dot represents one estimation, and in some cases of Cushing's syndrome more than one estimation was done on each patient. In the tumour section the open circles indicate patients with adenoma and the solid circles those with carcinoma. FIG. 2.—Levels of free 11-hydroxycorticoids in the urine of male subjects. Each dot represents one estimation, and in some cases of Cushing's syndrome more than one estimation was done on each patient. FIG. 3.—Levels of 17-oxogenic steroids in the urine of female subjects. Each dot represents one estimation, and in some cases of Cushing's syndrome more than one estimation was done on each patient. In the tumour section the open circles indicate patients with adenoma and the solid circles those with carcinoma. The vertical broken lines show the normal range. FIG. 4.—Levels of 17-oxogenic steroids in the urine of male subjects. Each dot represents one estimation, and in some cases of Cushing's syndrome more than one estimation was done on each patient. The vertical broken lines show the normal range.

$\mu\text{g./24 hours}$ (Fig. 2). In this small series the level of urinary 11-hydroxycorticoids did not appear to be related to the age of the subject.

Obese Group.—The excretion of 11-hydroxycorticoids was similar to that in the control group, and the ages of the subjects were comparable to those of the controls. In females the amounts ranged from 74 to 294 $\mu\text{g./24 hours}$, with a mean of 166 ± 53 (S.D.) $\mu\text{g./24 hours}$ (Fig. 1), and in males the range was from 92 to 352 $\mu\text{g./24 hours}$, with a mean of 245 ± 77 (S.D.) $\mu\text{g./24 hours}$ (Fig. 2). The urinary excretion of 17-oxogenic steroids was measured in most of these patients. In females it ranged from 3.4 to 24.8 mg./24 hours; 6 of the 41 estimations were above the accepted upper normal limit of 18 mg./24 hours (Fig. 3), as quoted by Brooks *et al.* (1963). One estimation fell below the accepted lower normal limit of 5 mg./24 hours, but the urine volume was low, and this result may have been due to the collection being incomplete. In the relatively small number of males the values all fell within the normal range of 6 to 22 mg./24 hours. The actual range found was from 7.0 to 18.4 mg./24 hours (Fig. 4).

Patients with Cushing's Syndrome.—The 11-hydroxycorticoid excretion was raised above normal levels in all 34 patients. In the 27 female patients the excretion ranged from 399 to 5,570 $\mu\text{g./24 hours}$, while in the seven male patients the levels ranged from 611 to 7,000 $\mu\text{g./24 hours}$ (Figs. 1 and 2). Particularly high values were found in patients with an adrenal carcinoma and in patients with hyperplasia associated with a non-endocrine tumour. There was a considerable day-to-day fluctuation in the urinary 11-hydroxycorticoid excretion in patients with adrenal hyperplasia. For example, one female patient showed levels on four separate occasions of 1,440, 638, 815, and 3,700 $\mu\text{g./24 hours}$. The excretion of 17-oxogenic steroids in both female and male patients showed a considerable overlap with the normal ranges. In a number of patients more than one estimation was made on different 24-hour urine collections. Only 29 out of the total of 51 estimations were above the upper limits of normal (Figs. 3 and 4). High levels were invariably found, however, in patients with an adrenal carcinoma and in patients with hyperplasia associated with a non-endocrine tumour.

Discussion

These results show that by measuring the urinary output of free 11-hydroxycorticoids a clear distinction can be made between patients with established Cushing's syndrome and those with simple obesity. This method therefore provides a relatively simple screening test, which can be used to decide whether patients with suspected Cushing's syndrome should be further investigated. Our results confirm the findings of previous workers that the urinary 17-oxogenic steroid excretion is often within the normal range in patients with Cushing's syndrome (Cope and Black, 1959; Brooks *et al.*, 1963; Cope and Pearson, 1965; Ernest, 1966; Ross *et al.*, 1966), and that, in addition, the levels in some obese patients are elevated (Cohen, 1958; Simkin, 1961; Baird, 1963; Gogate and Prunty, 1963).

The incidence of Cushing's syndrome and obesity is higher in women than in men, and this is reflected in the relative proportions of the sexes in this study. Furthermore, the normal ranges of urinary steroids differ between men and women so that it is necessary to consider the data separately.

In the control group the mean value for the free 11-hydroxycorticoids in women was 174 $\mu\text{g./24 hours}$, ranging from 78 to 311 $\mu\text{g./24 hours}$. In men the mean value was 229 $\mu\text{g./24 hours}$, the range being 108 to 396 $\mu\text{g./24 hours}$. These levels are very similar to those found by De Moor *et al.* (1962), who, using a comparable method of estimation, found a mean value for females of 179 $\mu\text{g./24 hours}$, and for males of 201 $\mu\text{g./24 hours}$. On the other hand, Gantt *et al.* (1964) have reported levels that are substantially lower than those quoted above.

Their mean level was 86.8 $\mu\text{g./24 hours}$ in 17 healthy adults between the ages of 20 and 40 years, with a range of 31 to 150 $\mu\text{g./24 hours}$. Their method involved a more complex schedule for washing the methylene dichloride extracts, and in our hands led to a reduction in the recovery of added cortisol from 95% to 80%, and to a 40% loss in the fluorescence of a urine specimen estimated by both methods. Presumably some of the more polar steroids which are estimated with cortisol in our method are removed by this technique.

The reliance which can be placed on the results of any scientific work depends mainly on the validity of the methods used to produce those results. Criticisms can be levelled against this fluorescence method for the estimation of 11-hydroxycorticoids, but its virtues far outweigh its disadvantages. It is accurate and precise, and is quick and easy to carry out. Six estimations can be completed in less than two hours. In contrast to the 17-oxogenic steroid estimation the presence of glucose in the urine does not interfere with this method.

The justification for its use as a measure of adrenocortical activity lies in the good correlation between this method and the isotopic estimation of the cortisol secretion rate, but it should be emphasized that this fluorescence method was originally proposed as a measure of free 11-hydroxycorticoids in the urine, and not of cortisol alone (Mattingly *et al.*, 1964). There is little doubt that other steroids are measured besides cortisol, and these include corticosterone and 20-hydroxycortisol. Indeed, cortisol may comprise only a small proportion of the total fluorescence in some urines. Espiner (1965), using paper chromatography and an internal isotope standard to correct for losses, found that the amount of free cortisol accounted for only 8 to 73% of the fluorescence measured in different urine samples. In addition there is a small amount of nonspecific substances included in the estimation. The total fluorescence increases with time if the urine is not deep-frozen within 24 hours of completing the collection, and the increase is greatest in infected urines.

Drugs administered to patients do not appear to interfere with these estimations, with the exception of spironolactone and mepacrine. Mepacrine may continue to be excreted for many days after cessation of administration (Freitas e Costa *et al.*, 1965); we found the same phenomenon in one patient on spironolactone who is not included in this series. It is well known that oestrogens raise the plasma levels of 11-hydroxycorticoids, and that high levels are found in women taking oral contraceptives (Metcalf and Beaven, 1963). It might be expected that this would affect the amount of free 11-hydroxycorticoids found in the urine, but the increase of plasma 11-hydroxycorticoids is due to an increase in the protein-bound cortisol which is not filtered through the renal glomeruli. In a small number of healthy women taking contraceptive pills, who are not included in our control group, the urinary excretion of 11-hydroxycorticoids at the end of the three-week cycle fell within the normal range at a time when their plasma 11-hydroxycorticoids were elevated. Nevertheless, if high urinary levels are found in patients taking contraceptive pills it is recommended that the treatment be stopped and a repeat estimation done a month later. Katz *et al.* (1962) found that an unconjugated 11-hydroxycorticoid—namely, 6- β -hydroxycortisol—was increased in the urine after oestrogen administration. This particular steroid is not measured by the fluorimetric technique used here, but their findings suggest that oestrogens produce an alteration of cortisol metabolism, and it is possible that this might result in an increased excretion of other unconjugated 11-hydroxycorticoids in the urine.

It is easy when introducing a new diagnostic test to use an elliptical argument in deciding its value; a suspected case shows a positive result in the new test, therefore the diagnosis is confirmed in that case, and therefore the test is useful in diagnosing such cases. This pitfall has, we hope, been avoided here. In all the cases of Cushing's syndrome the diagnosis was

confirmed by independent means. A raised midnight plasma 11-hydroxycorticoid level was found in all cases, and in 33 out of the 34 patients the morning plasma 11-hydroxycorticoid levels failed to suppress normally during the administration of 2 mg. of dexamethasone daily for 48 hours (Mattingly, 1963; Cope, 1966). Raised cortisol secretion rates were found in the 20 patients in whom this investigation was carried out, including the one patient who suppressed normally on dexamethasone. In the remaining 14 patients the diagnosis was ultimately confirmed at operation or necropsy. It was not practicable to carry out these investigations on all the patients with "simple" obesity, but a random sample of 20 obese patients showed normal midnight plasma 11-hydroxycorticoid levels and normal suppression during dexamethasone administration.

There is considerable controversy over whether adrenocortical activity is significantly increased in "simple" obesity. It has been shown in numerous studies that urinary corticosteroid excretion may be raised and that the mean cortisol secretion rate may be higher than normal, a few patients showing grossly elevated levels (Gogate and Prunty, 1963; Migeon *et al.*, 1963; Schteingart *et al.*, 1963; Dunkelman *et al.*, 1964; Copinschi *et al.*, 1966). It is possible, however, that the latter cases were atypical cases of Cushing's syndrome which could not be recognized from the clinical findings. Our results do not support the view that there is a marked deviation of cortisol secretion from normal in obese subjects, since their urinary 11-hydroxycorticoid levels are very similar to those in the control group.

The control group consisted of healthy adults and convalescent hospital patients not suffering from endocrine, liver, or renal disorders that might affect the excretion of steroids in the urine. Care was taken to ensure that these subjects were not stressed during the urine collection period, since both emotional and physical stress will temporarily increase adrenocortical activity and result in a raised urinary 11-hydroxycorticoid excretion. It should be remembered that this study has been based on the urinary 11-hydroxycorticoid excretion in adults and teenagers, and it is probable that the normal ranges will be lower in younger children. For practical purposes, however, this is of little importance, since Cushing's syndrome is rare in this age group.

Summary

Urinary 11-hydroxycorticoids were measured in 34 patients with established Cushing's syndrome, and the results compared with those found in 75 obese patients and in a control group of 109 subjects made up of healthy volunteers and convalescent hospital patients. Raised levels were found in all

the cases of Cushing's syndrome while normal levels were found in the obese group. Urinary 17-oxogenic steroids, on the other hand, showed a considerable overlap between these groups, and normal levels were not infrequently found in patients with Cushing's syndrome.

The fluorimetric estimation of urinary 11-hydroxycorticoids is a relatively simple and rapid procedure, suitable for routine clinical use. It provides a reliable screening test for patients with suspected Cushing's syndrome.

We are grateful to the Medical Research Council for financial support, and to Dr. K. Fotherby and Miss M. M. McCready for the 17-oxogenic steroid estimations. We are also indebted to our colleagues at the Hammersmith Hospital and the Royal Devon and Exeter Hospital for allowing us to study patients under their care.

Case of Tuberous Sclerosis and Haemorrhagic Retinopathy (with Fundus Photographs)

A. M. DYER,* M.B., CH.B., D.O.; R. HILL,† G.M., M.B., CH.B., M.R.C.P.GLASG.

R. M. ROWAN,‡ M.B., CH.B., M.R.C.P.GLASG.; W. O. G. TAYLOR,§ M.B., CH.B., D.O.M.S., F.R.C.P.GLASG.

Brit. med. J., 1967, 4, 398-399

Tuberous sclerosis is a genetically determined disorder (Duke-Elder, 1940) characterized by mental deficiency, epilepsy, skin fibromata, and maldevelopment. Patients may not always present with the complete form of the disorder. It is said that the disease is usually fatal, the majority of patients dying before the age of 24. The patient in the following case is 38.

Case Report

The patient, who was born in 1928, was said to have been well up to 1945, when she began to develop fainting attacks or fits. In August of that year she attended Ayr County Hospital, where it was noted that she was nervous and that her fits seemed to be related to menstruation. A provisional diagnosis of petit mal was made and $\frac{1}{2}$ gr. (32 mg.) of phenobarbitone was ordered. Subsequently the use of thyroid was also advised. The late Dr. J. N. Tennent also saw her repeatedly at this time. He reported normal vision and no refractive error, but "considerable swelling of the right optic disc; rather cystic-like on nasal side." The fields of vision showed a possible defect in the right upper nasal quadrant. X-ray film of the skull, however, showed possible enlargement of sella, though this was not confirmed on repeat. Six weeks after the initial observation it was thought that *both* optic discs were swollen, the right more pronounced, and in April 1946 Dr. Tennent noted a "tapioca grain appearance" of the right disc. In September 1949 stabilization of the fits on phenytoin sodium and phenobarbitone was carried out, and in October she was admitted to Ballochmyle Hospital for investigation. The abnormal findings were confined to the electroencephalogram, which was carried out at Killearn Hospital. The report stated: "Gross dysrhythmia with low voltage from all leads. This indicates marked cerebral dysrhythmia—attacks epileptic." Several fits occurred under observation, and a psychiatrist reported "major and minor fits preceded menses," and, the following week, "Intelligence below average but not defective. No gross emotional disorder." On his advice she was given phenytoin 400 mg. daily in divided doses, benzedrine 5 mg. at midday, and phenobarbitone 1 gr. (65 mg.) morning and night. These reduced but did not eliminate the fits.

In March 1956 she had a nocturnal fit, after which she was completely aphasic for 10 days. In May she complained of defective vision and was referred to the medical outpatient department of Heathfield Hospital. The complaint appeared to be glare; there was a history of several attacks of status epilepticus, and for the first time a facial rash was mentioned. There was no abnormality in the fundi, but an iron-deficiency anaemia was found and treatment with primidone suggested, because of the mixture of petit and grand mal, in addition to iron therapy.

At review the anaemia had improved but the patient failed to come into hospital for fuller investigation.

In 1961 she developed a persistent cough, and from January 1964 she felt weak and unwell and developed gradually increasing oedema. She was admitted to the medical ward at Heathfield Hospital on 24 February 1964.

On examination the positive findings were marked clubbing of fingers and oedema of hands and feet, slow speech, and rather poor intelligence. X-ray film of chest showed an area of consolidation in the right lower lobe and recent bronchopneumonia was suggested. Sputum culture showed pneumococci. X-ray examination of the skull revealed no abnormal calcification in the cerebral hemispheres. The blood picture showed severe anaemia, and a sternal marrow puncture was therefore performed. The latter showed appearances compatible with the diagnosis of megaloblastic anaemia, and treatment initially by blood transfusion and then iron by mouth with injections of folic acid was given. By 14 July 1964 her haemoglobin had risen (from 4.1 to 15.4 g./100 ml.). Phenytoin was continued.

Fundus examination on 25 February revealed haemorrhages and exudates in the left eye with drusen of the optic nerve head and one exudate. It was suggested that this indicated a vascular retinopathy and tuberous sclerosis. This diagnosis was later confirmed (Figs. 1 and 3).

On 20 November 1964 (Fig. 2) all haemorrhages and exudates had cleared, though the drusen in the other eye naturally remained unchanged (Fig. 3). Her visual acuity with correction was 6/5 right and left when last seen on 13 October 1966.

Discussion

It is tempting to conclude from the wording of J. N. Tennent's report in 1946 that he had in mind the actual diagnosis made in 1964. His detailed description of the appearance of the discs shows that there was no great change in them

FIG. 1.—Left fundus on 28 February 1964, showing numerous retinal haemorrhages, mainly in the nerve fibre layer, and some "exudates."

§ Consultant Ophthalmologist, Heathfield Hospital, Ayr.

over this long time, though the number of drusen (R—14, all nasal; L—2 nasal, 1 superior temporal) may have increased (see Reese, 1940).

The term "drusen" is a confusing one. There are several conditions in which this term is used (Duke-Elder, 1940), but as applied to the optic disc the word was first employed in German literature as *Drusenbildungen* ("granular formations," apparently a mineralogical term (Fuchs, 1951)). Parsons anglicized the word to drusen in an excellent comprehensive review of the subject (Morton and Parsons, 1903), but up to the time of his paper only two cases had been diagnosed ophthalmoscopically before pathological examination.

Nodules occur in the retina in tuberous sclerosis (Van der Hoeve, 1920, 1923), including the disc, but the specific type known as drusen of the optic disc was not connected with this disease until Reese made the suggestion in 1940.

The megaloblastic anaemia was presumably the result of a folic acid block from the diphenylhydantoin (see Goodman and Gilman, 1965). This type of megaloblastic anaemia is uncommon (Williams, 1963). It appears to require long-continued use of the drugs (Badenoch, 1954; Berlyne *et al.*, 1955)—as was the case here.

FIG. 2.—Left fundus on 20 November 1964, showing complete clearing of the haemorrhages. One drusen can be seen at the upper temporal margin of the disc.

As can be seen from the fundus photographs, with treatment of the anaemia the haemorrhages in the left eye cleared rapidly, with restoration of the visual acuity (Figs. 1 and 2).

FIG. 3.—Right fundus on 20 November 1964, showing numerous drusen on the nasal side of the disc.

Summary

A case is described of probable tuberous sclerosis, or Bourneville's disease, in a woman who presented at the age of 16 with major and minor epileptic seizures. She also showed adenoma sebaceum and drusen of the optic disc, low intelligence, temper tantrums, and hysteria. The fits were partially controlled by phenytoin, benzedrine, and phenobarbitone from the age of 21, but subsequently she developed megaloblastic anaemia which required treatment with folic acid.

We must express our thanks to the Department of Ophthalmology, Glasgow University, for the fundus photographs.

Medical Memoranda

Stellate Ganglion Block in Treatment of Total Blindness Due to Quinine

Brit. med. J., 1967, 4, 400-401

Stellate ganglion block has been successful in the treatment of a variety of conditions where disorder of the sympathetic supply to the head, neck, and upper extremity is a causative factor.

CASE REPORT

The patient, a single girl aged 17, thinking herself pregnant (erroneously as it happened) took 8 g. (125 gr.) of quinine hydrochloride in 24 hours (Day 1).

When seen on Day 3 there was no perception of light in either eye. The pupils were widely dilated and did not react to light.

FIG. 1.—Fundal photograph on Day 4 shows macular oedema, normal discs and vessels.

FIG. 2.—Visual field on Day 4 showing marked contraction.

The retinal arteries were not constricted. The optic discs were of normal colour, but the margins were blurred and there was macular oedema. Gastric lavage was performed. A bilateral retrobulbar injection of 100 mg. of acetylcholine was given followed by tolazoline hydrochloride 50 mg. and nicotinic acid 100 mg. four-hourly.

She was still completely blind that evening. The duty anaesthetist was consulted and stellate ganglion block decided on. The right side was blocked with 5 ml. of 1% lignocaine with 1:160,000 adrenaline, the anterior paratracheal approach (Davies, 1952) being used. Within a minute a positive Horner's syndrome was noticed and the patient could perceive light in the right eye. After about 10 minutes the left side was blocked with an identical result.

It was decided to repeat the stellate ganglion block at any time that the patient felt her vision was deteriorating, and it was performed on 19 separate occasions in seven days.

Day 4.—The fundi had not changed since admission (Fig. 1). Vision was 6/9 with the right eye and 6/6 with the left, but the visual fields were markedly contracted (Fig. 2).

Day 6.—Clearance of quinine was virtually complete (Fig. 3).

Day 9.—The visual fields continued to enlarge, but oedema of the retina and blurring of the disc margins persisted. Dichlorophenamide (Daramide) 125 mg. t.d.s. and potassium chloride 0.5 g.

FIG. 3.—Concentration of quinine as sulphate in the blood.

FIG. 4.—Visual field on Day 93. This shows some persistent restriction of the peripheral field.

daily was given to reduce retinal oedema. The patient noticed marked deterioration of vision at dusk.

Day 13.—Discharged from hospital. Pallor of both optic discs had developed with further constriction of the retinal arteries.

Day 19.—Vision almost normal and retinal oedema less marked.

Day 27.—Retinal oedema more restricted. Vessels were narrower and the disc was becoming a little pale.

Day 93.—Vision was subjectively normal, except for some difficulty in adaptation on entering a lighted room, but some constriction of the peripheral fields persisted (Fig. 4). A further fundal photograph is shown (Fig. 5). Hearing was assessed by an audiogram and was normal.

FIG. 5.—Fundal photograph on Day 93. There is continuation of the processes noted on Day 27.

COMMENT

There is a wide variation in tolerance to quinine, but symptoms are likely in anyone taking a single dose larger than 4 g. (60 gr.) (Polson and Tattersall, 1959). Most cases of quinine amaurosis in the United Kingdom follow its use as an abortifacient (Scott, 1953). There is no control over the sale of the drug.

There is a tendency for quinine amaurosis to recover (Duke-Elder, 1954), the likelihood being inversely proportional to the duration of blindness, and recovery may take months. Permanent blindness with optic nerve atrophy has been reported, however (Braveman *et al.*, 1948; Sir B. W. Rycroft, personal communication). The pathogenesis of blindness in quinine poisoning is a matter of dispute. Ballantyne (1917) thought quinine had a direct toxic effect on the retinal cells, particularly the rods, and that vasoconstriction was a secondary effect. Damage to the rods seemed to be confirmed by the deterioration of vision at dusk noticed in the present case. Ballantyne stated that visual loss occurs while the retinal vessels are normal in appearance and that vasoconstriction is a feature of the recovery phase. This is supported in our case, where arterial narrowing was not apparent until Day 9, six days after the onset of blindness. Many authors, however, point to the extreme constriction of the retinal vessels and believe this to be the cause of blindness by producing retinal damage. Some observers have

noticed the similarity to changes seen in occlusion of the central retinal artery (Turtz, 1957). Braveman *et al.* (1948), reporting a case in which blindness was permanent (and in which stellate ganglion block was not performed), noted persistent vasoconstriction.

Whatever the pathogenesis of amaurosis in quinine poisoning the only effective form of treatment appears to be that aimed at producing retinal vasodilatation. This is supported by experimental work in dogs. Giannini (1934) found that dogs could be protected from a blinding dose of quinine by the simultaneous administration of acetylcholine, while Vermes (1905) prevented blindness on one side only by previously sectioning the cervical sympathetic on that side.

Stellate ganglion block has been shown to produce dilatation of the retinal vessels. Wagener (1931) reported that retinal dilatation and miosis occurred with equal frequency after stellate ganglion block. Coston (1951) has shown its effectiveness in dilating the retinal vessels in his cases of embolism of the central retinal artery. Redslob *et al.* (1947) have also demonstrated its value clinically. They noted the dramatic improvement in both auditory and visual symptoms which followed bilateral stellate ganglion block in a patient who had aborted after the administration of 3 g. (45 gr.) of a quinine salt.

In a condition so dramatic, distressing, and with such crippling sequelae as quinine amaurosis the temptation to use polypharmacy is strong, and proved so in our case. This is ineffective to a greater or lesser extent. Stellate ganglion block, however, has proved to be universally effective, the degree of visual improvement being inversely proportional to the duration of blindness.

A plea is therefore made for it to be considered the first line of treatment for quinine amaurosis, and for it to be performed as soon as the diagnosis is made.

We wish to thank Dr. H. S. Brodribb and Dr. A. R. H. Worssam for their help and advice.

Scorbutic Megaloblastic Anaemia Responding to Ascorbic Acid Alone

Brit. med. J., 1967, **4**, 402

In recent years there has been discussion on whether the megaloblastic anaemia occasionally found in scurvy is due to deficiency of ascorbic acid or of folic acid. The diet taken by a scorbutic patient is usually also inadequate in folic acid. In many cases the apparent response of the megaloblastic anaemia to ascorbic acid may have really been due to the introduction of folic acid in the ward diet (Zalusky and Herbert, 1961). We here report the response of a scorbutic megaloblastic anaemia to ascorbic acid alone, the patient receiving a ward diet deficient in folic acid.

CASE REPORT

A 70-year-old man was urgently admitted to hospital in September 1963 complaining of painful swollen legs of three weeks' duration, with more recent spontaneous bruising. For four months before admission his general condition had deteriorated and he had lost weight. During this time his diet consisted of tea and toast with an occasional meat stew, and excluded fruit and vegetables. On examina-

tion the significant findings were pronounced anaemia, extensive bruising of both legs with perifollicular haemorrhages, cork-screw hairs, and hyperkeratosis. Both calves were very tender.

Investigations.—Haemoglobin 8.0 g./100 ml. M.C.H.C. 36%, M.C.V. 117 cu. μ . Reticulocytes 2%. Marrow: erythropoiesis was frankly megaloblastic and the iron stores were increased. Serum iron 125 μ g./100 ml.; serum vitamin B₁₂ 320 μ g./ml.; serum folate 1.7 μ g./ml. Ascorbic acid 500 mg. by mouth daily resulted in very little ascorbic acid excretion until the eleventh day.

The patient was maintained for the period of study on a folate-deficient diet composed of tea, bread, jam, egg, fish, chicken, minced meat, and potato. He was given 500 mg. of ascorbic acid daily by mouth. The haematological response is shown in the Chart. A good reticulocyte response was obtained. A series of marrow punctures showed a slow reversion of erythropoiesis to normal by the seventeenth day. The haemoglobin level showed a steady

rise, reaching 12.3 g./100 ml. in seven weeks. Frequent serum folate estimations were carried out, with repeatedly subnormal results except for one low normal figure. There was initially a dramatic improvement on ascorbic therapy, and then a gradual return to his normal state. Later a normal diet and folic acid 15 mg. daily were given.

DISCUSSION

The patient showed a complete response of megaloblastic erythropoiesis in scurvy to ascorbic acid alone.

Zalusky and Herbert (1961) treated a scorbutic patient on a folate-deficient diet with ascorbic acid and the megaloblastic erythropoiesis became more gross. Additional treatment with 50 μ g. of folic acid daily intramuscularly caused a reticulocyte response and rapid conversion of erythropoiesis. From this they adduced that the megaloblastosis found in scurvy is due to concomitant folic acid deficiency. In the literature we have found several reports of patients with megaloblastic anaemia and scurvy treated in a similar manner to ours, the diet during treatment with ascorbic acid being either the same as before admission to hospital (Bronte-Stewart, 1953; Goldberg, 1963), or deficient in animal protein and vitamin C (Brown, 1955; Neilson, 1960), or specifically folate deficient (Cox, Meynell, Northam, and Cooke, 1967). We therefore believe that dietary folic acid was not the cause of the response in these patients.

The experimental work of May and his colleagues showed that the megaloblastic erythropoiesis of monkeys fed on a diet deficient in vitamin C and folic acid reverted to normal when either vitamin was given (Sundberg, Schaar, and May, 1952), and that the explanation of this lay in the increased requirement for folic acid of the scorbutic animal (May, Hamilton, and Stewart, 1953). Haemorrhage and haemolysis, both features of scurvy, may lead to folate depletion in man (Rachmilewitz, 1965). The slow reversion of erythropoiesis to normal in our case and in that of Hyams and Ross (1963) favours the indirect nature of the effect of ascorbic acid on folate metabolism. The difference between the cases which have responded to ascorbic acid alone and the case of Zalusky and Herbert may be in the degree of tissue folate deficiency. A more fundamental role for ascorbic acid in folate metabolism has also been postulated (Vilter, 1964; Cox *et al.*, 1967), but this is still speculative.

We are grateful to Dr. A. Voss for his assistance with this case.

Current Practice

DISEASE OF THE DIGESTIVE SYSTEM

Postgastrectomy Problems—I

J. ALEXANDER WILLIAMS,* CH.M., F.R.C.S.

Partial gastrectomy has an excellent record in the treatment of peptic ulcer; in the well-chosen case its successes far outweigh its disadvantages. Nevertheless between 5% and 15% of patients continue to complain of serious symptoms after operation. As the number of patients subjected to partial gastrectomy in England and Wales in 1961 was approximately 26,000, if 10% of these develop some form of "postgastrectomy syndrome" then this will not be a rare problem. The commonest symptoms of patients who complain after gastrectomy are abdominal pain, vomiting, loss of weight, loss of energy, attacks of faintness, and diarrhoea. These symptoms usually do not occur singly but combine in an infinite variety of complexes that have become known as the "postgastrectomy syndromes." There is a good case for discarding the present concept of these as classical syndromes.

Many syndromes have been described, including those prefixed by the term dumping, afferent loop, and even efferent loop, long loop, and small stomach. To list these syndromes and describe their classical clinical pictures may help to place some of the known facts in an orderly fashion, but it is misleading in that it implies knowledge of the pathogenesis of the patient's symptoms. To categorize a patient as having the "afferent loop syndrome" implies that we know the cause of his symptoms and—often incorrectly—blame the afferent loop for their cause. Even the most closely studied and best understood postgastrectomy disease, the "dumping syndrome," has in its name an implied aetiology which explains only a small part of the syndrome. A further confusion is that the term dumping syndrome implies a different disease in different parts of the world. To some doctors the term is restricted to the feeling of faintness, nervousness, and flushing provoked by hypertonic foods, while others use it to encompass symptoms of vomiting, pain, and diarrhoea, or almost any symptom that occurs after gastric operations. Dumping may be a useful term to retain but only in the former limited sense.

This article will therefore be restricted to an evaluation and investigation of the symptoms of which patients complain, and readers who require descriptions of the variously defined syndromes are referred to the bibliography.

There are two groups of complications which usually present in different ways. Patients with abdominal complications such as pain, vomiting, or diarrhoea usually complain of these symptoms and demand attention from their doctor, while many of those with loss of weight, lack of energy, and the less dramatic symptoms of nutritional deficiency do not readily report for medical attention. However, the frequency of the nutritional complications is sufficiently high to justify a planned, even though infrequent, follow-up programme. The nutritional complications will not be considered in detail in this article.

Abdominal Pain or Discomfort

The patient who complains of continued or recurrent indigestion after an operation designed for the cure of this symptom needs careful investigation.

Once it is established that the pain or discomfort is associated with digestion and is not due to cardiac ischaemia or renal disease, it is then necessary to differentiate between recurrent peptic ulceration, oesophagitis, and biliary or pancreatic disease.

A carefully taken history and physical examination are essential, though these rarely establish the diagnosis with any certainty. Special investigations are therefore essential, and a programme should be designed to permit a thorough evaluation with the minimal discomfort to the patient. A full investigation is important, for it is never safe to assume that the presence of, say, oesophageal reflux or gall stones necessarily means that this is the cause of the patient's symptoms.

Haematological and Biochemical Screening

At the initial consultation a venous blood sample should be examined for haemoglobin and absolute indices. In addition, the level of serum vitamin B₁₂ should be estimated, as B₁₂ deficiency is almost invariably incompatible with recurrent ulceration. Estimations of serum bilirubin, alkaline phosphatase, and amylase are of value as indices of biliary or pancreatic disease. A high serum calcium level will suggest disease of the parathyroids and possibly of the pancreas. If laboratory facilities for plasma pepsinogen estimations are available this is a valuable screening test for recurrent ulceration.

The stools may be tested for occult blood, though I find this test of relatively little value even when repeated on successive days. A positive test can occur in so many conditions—stomal ulceration, erosions, oesophagitis, or carcinoma of the gastric remnant.

Radiography

The next least disturbing investigations are radiological; each patient should be studied with a plain abdominal film, a cholecystogram, and a barium meal. The erect and lateral abdominal films may show biliary or pancreatic calcification or distension of the gastric remnant or small bowel with air or fluid.

A cholecystogram is advisable in all patients. I have seen patients who have had vagotomy and even revision gastrectomy for symptoms that eventually were cured only by cholecystectomy. Gall bladder disease had not been suspected because the gall bladder had been judged normal at the original gastrectomy. It has been suggested that gastrectomy pre-

* Consultant Surgeon, United Birmingham Hospitals, External Scientific Staff, Medical Research Council.

disposes to biliary disease. Though this hypothesis lacks proof, the association is sufficiently common always to be considered in differential diagnosis and complete evaluation.

Barium contrast radiology is the most useful single investigation in the detection of stomal ulceration. Despite the popular belief that it is difficult to establish a diagnosis on barium meal examination, I have found that in all of ten cases of proved recurrent peptic ulceration there was a large crater demonstrated radiologically.

Some experts have advocated gastroscopy and gastro-photography as more reliable investigations than radiology in the diagnosis of these lesions, though endoscopy is less well tolerated by the patient than radiology. It is true that at gastroscopy it is often possible clearly to see the stomal ring and the jejunum beyond, and to see surface "erosions" at the stoma that are not detected on x-ray. However, it is also possible, even on an apparently satisfactory gastroscopy, to fail to see a large recurrent ulcer, while the examination is often made difficult by the reflux of bile and duodenal fluid. This is an examination for the few experienced experts. Too great an importance should not be given to the presence of stomal erosions. In my experience it is not justifiable to class these as recurrent ulceration and treat accordingly. It is only those cases with unequivocal stomal or jejunal ulcer craters that respond satisfactorily to surgical treatment. It is a commoner error to diagnose recurrent ulcer where none exists than to fail to diagnose it on a good x-ray examination.

In addition to the search for recurrent peptic ulceration on barium meal, it is necessary to look for evidence of hiatus hernia and oesophageal obstruction or reflux. The presence of oesophageal reflux or hernia does nothing more than suggest that the patient might have oesophagitis. The suggestion needs confirmation by the next series of investigations.

Secretion and Provocation Tests

Acid Secretion Tests.—The radiological sign of an ulcer is a constant barium-filled niche or pocket. The finding of such a niche, however "classical" its appearance, can be labelled as a peptic ulcer only if the patient's gastric secretion will permit peptic digestion. Stomal ulceration is often erroneously diagnosed in postgastrectomy patients who are hypochlorhydric or even achlorhydric. To substantiate the diagnosis of stomal ulcer, therefore, it is necessary for the secretion to be able to reduce the gastric pH to below 3.5. This can be tested either by measuring intragastric pH or by aspiration under conditions of maximal stimulation with histamine or gastrin or their analogues. In these tests it is essential to place the pH probe or aspirating tube accurately under fluoroscopic control. In practice some tests are unsatisfactory and a second test is always worthwhile if the diagnosis is in doubt.

Acid Provocation Tests.—It has been claimed that the presence of a stomal ulcer can be confirmed by lowering the pH of the gastric remnant by N/10 HCl infusion via a nasogastric tube and provoking the symptoms of which the patient complains. In my experience this test is unreliable and is more likely to produce the symptoms of oesophagitis than of stomal ulcer (Fig. 1).

FIG. 1.—Acid provocation test using N/10 HCl. For stomal ulcers (A) the test is not reliable; but it is valuable for oesophagitis (B).

The test is, however, of value in confirming that the patient's symptoms may be due to oesophagitis, which may be present even when it is not possible to demonstrate oesophageal reflux on one barium examination.

The oesophagitis provocation test is performed by slowly perfusing N/10 HCl into the lower oesophagus through a nasogastric tube. If this perfusion produces the symptoms of which the patient is complaining, then it is likely that these are due to oesophagitis. The test is also positive in patients with a bile oesophagitis; so the cause of the inflammation can be determined only by means of intra-oesophageal aspiration or pH monitoring. It is always advisable to confirm the final diagnosis of oesophagitis by endoscopy and biopsy. As these are the most unpleasant and hazardous of the investigations of oesophagitis they should be reserved for final confirmation.

Management of Recurrent Dyspepsia

Once having reliably evaluated the cause of the patient's dyspepsia, the problem of treatment remains. Stomal ulceration¹ and pancreatitis² require detailed consideration beyond the scope of this article. The treatment of gall bladder disease presents few problems but that of oesophagitis is difficult. Non-acid oesophagitis may be alleviated by a conversion gastrectomy with an interposed jejunal loop, while oesophagitis with a hiatus hernia may warrant surgical repair of the hernia. The results of surgery are, however, sufficiently unreliable to make it worthwhile first attempting symptomatic control by simple measures of posture, local anaesthetics, or polysiloxane compounds.

Vomiting

Patients complaining of vomiting after partial gastrectomy are usually difficult to evaluate and to treat. A few will have some form of organic obstruction and in them diagnosis and treatment are usually straightforward.

The symptoms that suggest an organic obstruction are unremitting vomiting with loss of weight and dehydration occurring in a patient who had previously been well since his gastrectomy. Upper intestinal dilatation may be detected on physical examination.

The x-ray signs are, once again, the most informative. On the erect and supine plain films dilatation and fluid levels may be seen in the upper gastrointestinal tract. Contrast studies with barium usually confirm the site of the organic obstruction and may indicate its cause. Recurrent ulceration, external compression of the bowel, or carcinoma of the gastric stump may be seen. Gastric carcinoma should always be suspected, as there is evidence to suggest that partial gastrectomy increases the risk of its development in patients with peptic ulcer. The radiological picture is often confusing, and suspicion of carcinoma should always lead to confirmatory tests by exfoliative cytology or endoscopy. Ulcerogenic endocrine tumours or "retained gastric antrum" should also be suspected, particularly if gastric acid secretion is high.

The treatment of an organic obstruction is almost invariably surgical. Extrinsic obstruction from bands of adhesions respond well to reoperation only when there is unequivocal evidence of proximal dilatation. The patient with vomiting and no definite sign of obstruction who is subjected to reoperation and has only bands of adhesions divided is rarely cured for long of his symptoms. It is likely that his vomiting is not due to the adhesions but rather to one or more of the many factors discussed below.

No Organic Obstruction

When, as in the majority of patients complaining of vomiting after gastrectomy, there is no x-ray evidence of obstruction,

evaluation and treatment are much more difficult. The so-called "afferent loop syndrome" is classically described as post-cibal discomfort or pain, relieved by vomiting bilious fluid, and associated with weight loss and malabsorption. The suggested aetiology is an intermittent obstruction of the afferent loop of a Billroth II type gastrectomy. X-ray studies of patients with copious bile vomiting show that there is no afferent loop obstruction and that symptoms occur when the stomach is distended by the juice ejected rapidly from the afferent loop. In 19 patients with these symptoms abolition of the afferent loop by conversion to a Billroth I gastroduodenostomy has not always cured the symptoms. True afferent loop obstruction does occur but is rare. It is uncommon to find a surgically remediable cause for the symptoms of nausea and vomiting after gastrectomy. In those patients with no radiologically demonstrable obstruction it is important to study the emesis threshold, which varies widely.

Three factors need to be considered: emotion, cardio-oesophageal competence, and gastric sensitivity.

The emotional factors are the most difficult to assess, but they are probably the most important. Some patients give a history of easy vomiting since childhood and were often subject to emotional or travel sickness. Vomiting was often a predominant symptom before gastrectomy, even in the absence of any ulcer stenosis. Other patients experience vomiting later in life as a manifestation of endogenous depression.

Cardio-oesophageal incompetence may be one reason why some patients with nausea vomit easily. Incompetence may have been present before operation; however, there is some evidence that partial gastrectomy interferes with normal competence, possibly by opening out the cardio-oesophageal angle. The incompetence may be assessed by barium examination, but because it can be an intermittent phenomenon it may not easily be detected.

Some patients have a stomach or stomach remnant that is, in some way, more than normally sensitive to stimuli. The stimulus may be distension, but in some cases it appears to be by direct mucosal stimulation. Patients with bilious vomiting after gastrectomy appear to be sensitive to the presence of duodenal juice in the stomach. If their symptoms are provoked by a meal, it is often possible to aspirate bile-stained fluid from their stomach and so relieve their symptoms. The symptoms are brought on again by reintroducing the fluid back into the stomach. This fluid will provoke nausea in another patient with the same symptoms, whereas a post-gastrectomy patient without symptoms of bile vomiting appears to be unaffected if the fluid is introduced into his stomach. It seems likely that the components of this fluid responsible for producing symptoms are bile salts.

Treatment of Non-obstructive Vomiting

A complete appraisal of the patient's nutritional state must be made, with particular reference to any deficiencies of iron, vitamin B₁₂, and folic acid. Correction of deficiencies and improvement in the patient's health and feeling of well-being are sometimes all that is required to control the nausea and

vomiting. When indicated, treatment for depressive neurosis with anti-depressant drugs should be the next line of treatment. In the emotional "easy vomiter" the first line of treatment should be the anti-emetic drugs of the dimenhydrinate or prochlorperazine variety.

FIG. 2.—Vomiting caused by excess regurgitation of bile into the gastric remnant after meals (A). Treatment is by diversion of the bile away from the stomach.

Where this initial treatment is not indicated or fails cardio-oesophageal competence should be assessed by barium meal examination. Regurgitation of bile into the stomach is assessed by tube aspiration and may be confirmed by barium-potato-meal examination. Testing the provocation effect of intragastric bile or taurocholate solution may also be helpful. A small number of patients will then be found in whom gross regurgitation of bile into the gastric remnant appears to be the main cause of their symptoms. These can be effectively treated surgically by operations designed to prevent bile regurgitation, such as jejunal loop interposition or roux-en-Y conversion (Fig. 2).

(This article will be concluded next week, together with a list of references and a bibliography.)

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Mycosis Fungoides

Q.—What treatment is there for mycosis fungoides?

A.—Mycosis fungoides is a malignant reticulosis which involves predominantly the reticulo-endothelial system of the skin at all stages of its prolonged course. It is a distinct entity, histologically and clinically, like Hodgkin's disease, and like it may occasionally terminate in other patterns of reticulo-endothelial disorder. Unfortunately the term is still sometimes misapplied to cases which are more appropriately classified with other reticuloses, merely because they show unusual features. Obviously no advice on treatment can be valid unless the diagnosis has been reliably established. A useful and well illustrated account of mycosis fungoides appears in *Cutaneous Manifestations of the Malignant Lymphomas*.¹

In most cases there is a distinctive "pre-reticulosis" stage which characteristically lasts many years. During this stage only symptomatic measures are available. There is no evidence whatever that vigorous treatment modifies the subsequent course, and it may do harm.²⁻⁴

During the malignant stage radiotherapy is the treatment of choice. The dose given to each lesion should be the smallest which is effective, and, since the disease is highly radiosensitive the dose can usually be very small indeed. Patients' lives are sometimes shortened by the mistaken application of unnecessarily high doses in a disease which will almost inevitably recur at intervals at the same or other sites. Such recurrences are not prevented by high dosage. Conventional radiotherapy is usually employed, but when it is available beta-ray therapy is preferable, and is in my opinion the treatment of choice.

When the disease is widespread the beta-ray therapy is still often appropriate. It is much better tolerated by the patient than the antimitotic agents which must be employed if beta ray is not available.

Brass as Irritant

Q.—Is an allergy to brass commonly met with, and could it be the origin of an apparently universal superstition that a brass finger-ring will poison the wearer?

A.—Brass is an alloy of copper and zinc. Allergy to it in the true immunological sense is almost unknown. Men working with brass develop brass "ague" and skin rashes.¹ These are due to irritant effects and not to allergy.

Much brass is impure, and the impurities are thought to be responsible for some of the irritant effects. The superstition that a brass finger-ring will poison its wearer has no foundation in fact.

Hepato-lenticular Degeneration

Q.—What are the chances of parents who have lost a child with hepato-lenticular degeneration having another child with the disease?

A.—Hepato-lenticular degeneration (Kinnier Wilson's disease) is an autosomal recessive condition.¹ The recurrence risk is one in four.

REFERENCE

- 1 Bearn, A. G., *Ann. hum. Genet.*, 1960, 24, 33.

Epithelioma Adenoida Cysticum

Q.—The maternal grandfather of a patient with epithelioma adenoida cysticum had the condition. The patient's mother had it, and her sister had two daughters with the condition and three sons without it. The patient is one of two sons and his brother is healthy. What is the risk of the patient's children having the disease?

A.—Epithelioma adenoida cysticum is probably an autosomal dominant condition. Some families, including this one, are compatible with X-linked intermediate inheritance, but in others this is excluded by male-to-male transmission of the condition. In either case there is a substantial risk to offspring. If the condition is autosomal the risk to offspring is one in two, regardless of sex, and if it is X-linked there is no risk to sons but all daughters will be heterozygotes (though not necessarily clinically affected).¹⁻³

Cervical Smear in Early Pregnancy

Q.—Is taking a smear for cervical cytology contraindicated in early pregnancy?

A.—There need be no fear that taking a cervical smear in early pregnancy might provoke a miscarriage. In the early days of cervical cytology there was some doubt whether in pregnancy benign changes could be distinguished from malignant ones. Most authorities now consider that cervical smears can be interpreted in exactly the same way during pregnancy as in the non-pregnant woman.¹

The question, however, of whether, having found repeatedly positive smears in early

pregnancy, it is desirable to pursue the diagnosis to the extent of performing cone biopsy without delay, is more difficult to answer. Some of the arguments have recently been summarized.^{1,2} Because of the complications that are associated with up to one-third of the cone biopsies carried out during pregnancy, it has been suggested that taking cervical smears is best delayed until the puerperium, when a positive cervical smear can be acted on by conization without fear of the consequences.

In young women of low parity this argument is probably justified. In older women, however, and particularly in those of high parity or in those who have had irregular or post-coital bleeding, there is every reason for taking a cervical smear and, if necessary, for cone biopsy during pregnancy.

Brucella in Milk

Q.—Is it hazardous to drink raw milk infected with brucellosis but diluted by bulking so that culture is negative, though positive ring and guinea-pig tests are positive?

A.—Yes, it is hazardous. If a guinea-pig shows evidence of infection with brucella after inoculation it must mean that the milk sample contains live brucella organisms, and is therefore capable of causing human infection.

The bulking of milk of a herd containing a few animals excreting brucella dilutes out the antibodies in the milk, and this may be to the extent of rendering the milk ring test (M.R.T.) negative while both cultural and biological tests remain positive. Conversely a persistently positive M.R.T. can occur when the cultural and biological tests are constantly negative. This is due either to intermittent excretion of the organism by the udder or to adult vaccination with Strain 19. This can be determined by the herd inoculation history and by various serological tests on the individual animal.

Endotracheal Tubes

Q.—For how long can oral endotracheal tubes be left in position with safety in (a) adults and (b) babies, and are plastic tubes less irritant than rubber ones?

A.—Unfortunately it is impossible to be quite sure how long an endotracheal tube can be left in place without the risk of damage to the larynx and trachea. Experience shows that in both adults and babies tubes can be safely left for a period of up to 48 hours. Beyond that the risk of subglottic stenosis, the most important complication, becomes more than a remote possibility.¹ Plastic tubes seem to be less irritant than rubber ones, though plastic ones are also capable of causing damage.

Book Reviews

Immunization: its Benefits and Dangers

The Hazards of Immunization. By Sir Graham S. Wilson, M.D., LL.D., F.R.C.P., D.P.H. (Pp. 324+x. 45s.) London: Athlone. 1967.

The subject of the hazards attendant upon immunization procedures is one that few have hitherto had the courage to tackle. Fear of providing fuel for the sometimes justifiable arguments of the anti-vaccinationists may have constituted the main and very obvious objection, but the formidable nature of the task, entailing the collection and perusal of countless records, must have also deterred many. That this nettle has at last been grasped and by so eminent an authority as Sir Graham Wilson, who is equipped by a lifetime of almost unique experience in this field to give a broad and impartial presentation of the subject, is something that will be universally welcomed. Although he had long had in mind the need for a book of this nature, it was a remark made by a university lecturer in bacteriology to the effect that the Lübeck disaster of 1930 was the first recorded instance of disaster associated with a vaccine that finally impelled the author to make a compilation of all recorded accidents occurring after immunization, a long series of which could be found in the 40 years before 1930. The result of his labours was incorporated in a series of Heath Clark lectures given at the London School of Hygiene and Tropical Medicine in 1966.

The subject matter is conveniently divided into six main sections—namely, (1) normal toxicity, (2) faulty production, (3) faulty administration, (4) abnormal sensitivity of the patient, (5) allergic phenomena, and (6) indirect effects such as damage to the foetus or provocation of disease. Under faulty production and faulty administration very full and detailed accounts are given of the various mishaps, some unavoidable, others the result of carelessness or stupidity, which have shaken the confidence of both lay and medical men from time to time but which nevertheless provided the experience from which modern techniques have been evolved. Examples of “inherent toxicity” have nearly all followed the use of toxin-antitoxin mixtures (T.A.M.) against diphtheria which became unstable on freezing, liberating toxin. Under “inherent infectivity” the author examines the failure to inactivate the early Salk vaccines (owing to delay in recognition of the limitations of formaldehyde as a disinfectant in the presence of protein) which finally culminated in the Cutter incident. There may not be general agreement with Wilson in his view that the case against both the Salk and Sabin vaccines as a cause of poliomyelitis remains unproved, but none could doubt that the presence of Simian viruses, such as SV 40, which may be found in both Salk and Sabin vaccines, is undesirable, though there is as yet no evidence that they are harmful to human beings. Extensive accounts are given of the many incidents in which vaccines or antisera have become contaminated during production; these largely resulted from the

introduction of staphylococci, but instances of contamination of plague vaccine, diphtheria antitoxin, and smallpox vaccine with tetanus bacilli are also given. Serum hepatitis is a reminder of the ease with which virus agents may contaminate materials and apparatus, with unhappy results. Yet the evolution of modern techniques, based on lessons learned from such experiences, the use of disposable syringes and needles, and constant vigilance on the part of those who administer the agents should go far to eliminate the possibility of such events recurring in the future. Indeed, a chapter dealing with contamination originating in the operator reminds us of the need to impress upon undergraduate and graduate alike the dangers that may arise for patients treated by doctors and nurses who are themselves suffering from infections, particularly sore throats and boils.

A large section of the book is devoted to accounts of the various types of allergic manifestation that may result from immunization; these include the once all-too-common serum sickness as well as serum neuritis and post-vaccinal neuritis. An account of the history of encephalomyelitis following smallpox vaccination is of outstanding value. The distinction is clearly made between cases of encephalopathy found in children under 2 years of age and those of encephalomyelitis of the demyelinating type which occur predominantly over this age, and the three main views on pathogenesis are critically examined. Methods of prophylaxis based on the use of a concomitant dose of dried gammaglobulin or preliminary vaccination with a killed vaccine, the efficacy of which is not yet proved, are rightly dismissed in favour of the simpler and more straightforward measure of restricting vaccination to the first two years of life. The occurrence of encephalomyelitis following the use of other vaccines is also discussed. Of current interest is that which is associated with pertussis immunization. Although little is known about the histopathology, it is clear that this is a special form of encephalitis, more of a toxic than of an allergic nature; the clinical manifestations are indistinguishable from the encephalitis which may follow a natural attack of the disease, and it is therefore logical to assume that both are the result of the action of the endotoxin of the bacillus. The high incidence of neurological complications following the use of the vaccine in Sweden convinced Ström that its use was not justified. Indeed, these tragic sequelae of whooping-cough immunization compel a critical review of the position, and the author considers that in view of the low mortality and lack of any positive evidence that the vaccine is successful there is a good case for discontinuance.

A very full account of anaphylactic reactions following the use of both sera and vaccines is given. Under conditions of mass immunization these are inevitable, but careful

inquiry as to a history of allergy, and a preliminary small subcutaneous test dose, may go far to prevent such reactions in individual cases.

While there can be no doubt that much more benefit than harm has accrued from immunization procedures they can never be regarded as wholly free from danger, and Wilson insists that they should never be used as a means of avoiding the “tedious, troublesome, and sometimes expensive process of improving personal and environmental hygiene.” He strongly condemns mass immunization with its inevitable masking of much latent infection, and, as was seen in the mass immunization that attended the smallpox scare of 1962, much in the way of allergic reactions or more sinister complications such as eczema vaccinatum or progressive vaccinia. A very thorough programme of immunization during childhood is essential if mass immunization is to be avoided, and in this respect Wilson considers that we have much to learn from the Soviet Union, where children attend for general examination, immunization, and repeat immunization once a year up to the age of 7 years.

This is a work of outstanding merit. Its scholarly nature, the masterly exposition of a subject on which there is widespread ignorance, the compilation of records and facts of intense historical interest, and the very fair and balanced assessment of present knowledge render it a landmark in medical literature.

A. MELVIN RAMSAY.

Testicular Function

Endocrinology of the Testis. Ciba Foundation Colloquia on Endocrinology. Vol. 16. Edited by G. E. W. Wolstenholme, O.B.E., M.A., F.R.C.P., F.J.Biol., and Maeve O'Connor, B.A. (Pp. 331+xiii; illustrated. 60s.) London: J. & A. Churchill. 1967.

When one considers the embarrassing volume of new work on other endocrine glands, it is surprising how little is written about the testis, though some notable advances have been made in recent years. Of these, few have found clinical application at present, and this book, excellent though it is and stuffed full of basic learning, apparently takes the clinician no nearer to the solution of his own problems than he was 30 years ago.

It is important to stress the word “apparently,” for a careful perusal will disclose an occasional shaft of light, albeit pencil-sized, that may one day expand into a beam capable of illuminating the problems of the physician. There is hope in the work of B. Lunenfeld on the effects of human menopausal gonadotrophin in azoospermia, and in the discussion after Dr. L. M. Fishman’s paper of the role of the testis in oestrogen production. There appears to be a presumption that the oestradiol comes from the Leydig cells, but as R. G. Harrison pointed out it might come from the Sertoli cells, about which surprisingly little seems to be known. The work

of N. Törnblom, who thought that it came from the germinal epithelium, seems to have been forgotten. The discussion on the effects of cirrhosis on the plasma testosterone level certainly reached a clinical level.

Nevertheless, this is a book for the physiologist, for whom it is a necessary reading, rather than for the clinician.

RAYMOND GREENE.

The Case for "Homo Sportivus"

Energy, Work and Leisure. By J. V. G. A. Durnin, M.B., D.Sc., and R. Passmore, M.D. (Pp. 166+ix; illustrated. 25s.) London: Heinemann. 1967.

The contents of this book are indicated in the title, and are certainly of importance to everyone practising or associated with medicine. The authors, who are widely known for their extensive work on energy requirements, published a paper in *Physiological Reviews* in 1955 on "Human Energy Expenditure."¹ This paper is constantly quoted, and may reasonably be described as classic, using the Oxford English Dictionary definition of the term as "of the first class; of allowed excellence."

The book the authors have now prepared is a logical development of their famous paper and will further extend their reputation. I have read it with pleasure and profit, because the book is clearly written and the many tables are so well presented, and because I have learnt much about a subject which I considered to some extent my own. This does not mean I agree with everything; indeed such agreement could imply criticism, since there are many controversial aspects of the general problems of energy balance in man. The authors have some hard things to say about basal metabolic rate, and question the validity of the usual standard tables. They prefer to use the term "resting" metabolism, and have prepared a table of standard values based on body weight and an estimate of body fat. The argument is presented vigorously and attractively, and many will agree that the concept of "basal" metabolic rate is due for criticism.

The most important part of the book is the collection and presentation of energy expenditure figures. These are based on the thousands of measurements made by the authors, as well as on material published by others. Tables are not usually exciting in themselves, but the authors have succeeded in making theirs interesting to the general reader as well as invaluable to the specialist.

I warmly recommend this book, and I hope it will be widely read. The housewife can learn the calorie cost of shopping and cooking; the industrial medical officer will be concerned with the energy expenditure of various occupations; and all of us can read with concern the authors' comments on *Homo sedentarius*. We are evidently lazy creatures; Dr. Durnin and Dr. Passmore wish to convert us for our own good to *Homo sportivus*.

O. G. EDHOLM.

Renal Pathology

The Kidney. Edited by F. K. Mostofi, M.D., and David E. Smith, M.D. (Pp. 592+xiii; illustrated. £7 18s.) Edinburgh and London: E. & S. Livingstone. 1967.

This book is the sixth of a series of monographs published by the International Academy of Pathology, and is a notable advance in detailed description of renal pathology. It is written by 33 distinguished authors, 23 of whom are American workers. Dr. E. M. Darmady, who wrote an important and lucid chapter on the renal changes in some metabolic diseases, is the only contributor from this country, but several of the other authors were trained in Britain.

The book is divided into three sections. The first deals with the general pathology of renal disease, the second with immunological injury to the normal and the transplanted kidney, and the third with variations in renal pathology in relation to geography and climate.

All of the 28 chapters are clearly written and excellently illustrated. The book is not suitable, nor is it intended, for the beginner in renal disease and pathology. It will, however, be invaluable to any pathologist interested in modern advances in diseases of the kidney, and to the clinician using the technique of percutaneous renal biopsy. The authors have not felt restricted to keep to established facts, but have often indulged in valuable and well-informed speculations on the advancing fronts of research on renal pathology.

The single fault of the book is well documented by Dr. F. K. Motofi in the preface. This is the lack of uniformity of terminology to illustrate the extent of both renal and glomerular involvement in disease. One important message would seem to be the necessity for an international committee to standardize nomenclature in this important branch of pathology.

M. D. MILNE.

Dream Analysis

Studies in Analytical Psychology. By Gerhard Adler, Ph.D. (Pp. 250; illustrated. 25s.) London: Hodder and Stoughton. 1966.

With the exception of a new preface and a foreword by Jung, from the German version of 1952, this edition for "technical considerations" is unchanged. For the author, this is regrettable. Given the opportunity he would have laid more emphasis on the analysis of the transference and altered details of procedure such as the number of weekly interviews. Nevertheless, the greater part of the earlier work is still valid and the author is convinced that dream-analysis holds its place as the main clinical tool for those who practise analytical psychology.

Jung was the first clinician to encourage his patients to give visible form, through painting and drawing, to the imagery of their dreams. To his surprise he found that those in the second half of life welcomed this form of expression. Not infrequently the urge to paint pictures or to make models arises spontaneously. For generations patients on their own initiative have produced pictures which were dismissed as meaningless scribbling.

Jung, however, proved the therapeutic value of such daubs.

Adler amplifies Jung's work, and his commentary upon the series of nineteen pictures, here produced, is a notable contribution to present-day investigation of the unconscious. Through the detailed analysis of a dream he demonstrates the significance of Jung's hypothesis of the collective unconscious and how the technique of *active imagination* may be used to bridge the gap between the ego and the non-ego.

Psychiatrists, even those without experience of psychological analysis, will find the well-presented case histories full of therapeutic hints. One thing becomes evident—the need to examine ego psychology in conjunction with the psychology of the personal and the collective unconscious.

This lucid study of the theory and practice of analytical psychology can be recommended to every psychotherapist whatever his affiliation to this or that "school."

E. A. BENNET.

Bronchoscopic Appearances

Atlas d'Endoscopie Bronchologique. Aspects Normaux et Pathologiques. By Jean Ioannou. (Pp. 64+vi; illustrated. 60 F.) Paris: Masson. 1967.

This excellent atlas of bronchoscopic appearances will be of value to all interested in chest disease or in endoscopy. Printed on high-quality paper, the text, in French, is short and describes the anatomy and the illustrations. Ninety reproductions of colour photographs, each 2 in. (5 cm.) square, accurately illustrate inflammations, neoplasms, and sequelae of operations. Similar black-and-white reproductions demonstrate normal anatomy and its variants and some less common diseases.

The student of bronchoscopy will find these pictures a useful guide; but he should remember that the camera records all it sees, and does not always mirror the emphasis that the surgeon's eye places on salient features—an emphasis which the painter can record; nor under the difficult circumstances of endoscopy can the camera always demonstrate perspective. Neither surgical nor photographic techniques are described, nor are any details of apparatus used given. There are no illustrations of foreign bodies in the air passages.

The photographs of tuberculous endobronchitis are especially welcome. This condition is seldom seen since its dramatic response to streptomycin therapy was recognized, but it remains important and an occasional diagnostic trap. British readers will be glad to note reference to the bronchus of Nelson. This eponym, seldom used in current English literature, commemorates the young thoracic surgeon who died a generation ago of an overwhelming infection due to a finger-prick received during an operation.

Dr. Ioannou records that of 40 patients he examined after tracheostomy, two-thirds showed important endoscopic lesions when apparently healed, confirming the now widely held opinion that the after-effects of this easily undertaken procedure may be serious.

An endoscopic photograph or a series can profitably form part of a patient's case record dossier. Those who are considering such a practice should turn to this atlas in the hope of emulating the high standard it sets.

M. MEREDITH BROWN.

"A Tentful of Scientists"

Reflections on Research and the Future of Medicine. A Symposium and Other Addresses. Edited by Charles E. Lyght, M.D. (Pp. 209+vii; illustrated. 81s.) London: McGraw-Hill, 1967.

This book is the record of a two-day colloquium on the occasion of the dedication of new research buildings at the Merck Sharp and Dohme research laboratories at Rahway, New Jersey, in May 1966. The speakers on the first day were Sir Macfarlane Burnet on autoimmune disease, E. L. Tatum on molecular biology and nucleic acids, F. O. Schmitt on molecular dynamics and brain function, and Sir George Pickering on degenerative diseases. On the second day W. H. Gadsden on research and public responsibility, M. Tishler on the challenge of pharmaceutical research, E. B. Chain on the quest for new biodynamic substances, H. W. Gadsden on the role of research at Merck, and Sir Henry Dale looked back to similar occasions at Merck in 1933 and 1953.

Americans have a particular affection for ceremonies of commencement, graduation, dedication, and rededication, which are of the nature of corporate acts of homage to education, science, or research as the case may be. The ceremonies are inspiring to the participants, but accounts of them, like other *Festschriften*, do not make particularly good reading.

Björck some years ago demonstrated by actual experiment how difficult it is even for young men to predict the future of medicine, and the speakers at Rahway were all senior. One of the photographs with which the book is illustrated is entitled "A Tentful of Scientists at the Rahway Dedication Ceremonies," and that is perhaps a good description of the book as a whole.

L. J. WITTS.

Disabled Children — Speech and Vision

Assessment of Cerebral Palsy. Vol. 2. By K. S. Holt, M.D., M.R.C.P., D.C.H., and J. K. Reynell, B.Sc., Ph.D. (Pp. 187+viii; illustrated. 40s.) London: Lloyd-Luke, 1967.

This Volume 2 is an excellent and authoritative yet easily read guide to the assessment of vision, hearing, language function, and intelligence in disabled children. As such it provides a useful reference volume to all the lay and professional workers involved in this important field.

It must be emphasized that apparently normal children may require assessment in their early years lest they should be victims of some slight perceptual or other disability which interferes with psychological development. For this reason teachers, social workers, and also parents should look through this book.

W. RITCHIE RUSSELL.

Doctor in India

Doctor Sahib. By Stephen Kerry. (Pp. 204. 30s.) London: Cassell, 1967.

In the late nineteen thirties, with the Government of India Act on the stocks and with independence apparently just round the corner, the Secretary of State for India announced the creation of new clinical civil posts in India reserved for European members of the Indian Medical Service, and started a recruiting drive for high quality officers with a promise of only brief military service in pleasant stations of the applicant's own choosing. This extraordinary appeal was most successful; a number of highly qualified "registrar types" from Great Britain, Canada, and Australia responded, and the I.M.S. had an intake of as high a quality as it ever had in its heyday.

Those of us who, as senior teachers, had for many years been training Indian doctors to take over the highest posts were somewhat disconcerted, and Indian political leaders and the entire Indian medical profession responded with anger and indignation at this apparent *volte face*. This move, in fact, hardened the

determination of leading Indian statesmen to abolish an all-India medical service when independence was achieved. They did so—a fact which some of them regret today.

One of this group has published his autobiography under the pseudonym of Stephen Kerry, and the account of his short prewar service in a popular hill station at a Gurkha battalion headquarters, and later as a civil surgeon in Bihar, makes compelling reading. The book has been deservedly acclaimed in the British press as eminently readable, fascinating, and absorbing, and is so well written and slanted to interest and to titillate the non-medical reader that one suspects the collaboration of a skilled professional writer.

The accounts of the investigation and control of an outbreak of cholera in a remote village in the Himalayas is very well done indeed, and the scene of famine and epidemic on the plains of Bihar are only too topical today. One of the better aspects of our work in India was the control of jails by medical men. As a young man devoted to a surgical career Kerry detested his jail duties, and the gallows is used inevitably with great effect in this para-autobiography.

One need not accept every incident as factual, but the general picture painted represents its period accurately; the busy absorbing life of a civil surgeon and district medical officer in India is skilfully depicted. *Doctor Sahib* is a moving but unsensational story of the life of a young introspective idealist in full sympathy with Indian aspirations. It is certainly the best of the "doctor" books published since the war.

GEORGE R. MCROBERT.

In his latest novel, *The Facemaker*, Richard Gordon recounts the fortunes of a plastic surgeon up to the outbreak of the first world war. Though at once self-assertive and priggish, the hero, Graham Trevoise, often engages the reader's sympathy owing to the prejudice that he meets from professional colleagues and social acquaintances. Forsaking the comic vein from which he dredged *Doctor in the House* and many irreverent successors, the author presents his characters now in a serious if no less recognizable setting. *The Facemaker* is announced as the first of a trilogy, and is published by Heinemann (pp. 244: 25s. net).

Books Received

Review is not precluded by notice here of books recently received.

Bedsore. By B. N. Bailey, M.B., B.S., F.R.C.S. (Pp. 130+vii; illustrated. 50s.) London: Edward Arnold, 1967.

Middle Articles

MEDICAL HISTORY

Tercentenary of Blood Transfusion

Sir GEOFFREY KEYNES, M.D., F.R.C.S.

Brit. med. J., 1967, 4, 410-411

In July 1667 Jean Denis, Professor of Philosophy and Mathematics at Montpellier and Physician to Louis XIV, sent a letter to the editor of the *Philosophical Transactions* of the Royal Society of London. This was a translation of "Copie d'une lettre touchant une nouvelle Manière de guérir plusieurs Maladies par la Transfusion du Sang," addressed

power. He then proceeded to state that, though transfusion of blood may have been conceived in other parts, "it is notorious that it had its birth first of all in England," through the hands of Dr. Lower and Dr. Edmund King, who had published accounts of it in November and December 1666. Denis's letter had, it seems, "come abroad" in July 1667, but it was omitted from most copies of the *Transactions*. In this manner a battle of priorities began, and it might be doubted whether the three hundredth anniversary of the practice of blood transfusion should be noticed in 1966 or 1967. From the fact that the present article is published in 1967 it may be guessed that the second date is to be preferred. It is not due to an oversight.

Denis himself in his first sentence emphasized that the conception of transfusion happened "about ten years ago in the illustrious Society of *Virtuosi* which assembles at your house," and that the Society had received Denis and a friend as visitors to see the experiments. As is well known, the investigations were initiated by Dr. (later Sir Christopher) Wren, who suggested injecting various liquors, such as milk or beer, into the circulation of animals. Subsequent experiments were carried out chiefly by Dr. Richard Lower, accounts of these being published in a series of papers in the *Philosophical Transactions*. Lower was a careful investigator and limited his experiments mainly to transfusing blood directly from an artery of one dog to the jugular vein of another. In this way he showed that a dog could be exsanguinated to the point of death and then be completely recovered by transfusion. He rightly concluded that the "most probable use of this Experiment" would be for replacing blood lost or for rectifying corrupt blood.

Once Denis's letter became known the London experimenters were not slow to complain, in the *Transactions* for 21 October 1667, that he was claiming a priority due to them. This seems ungenerous, since Denis had deliberately assigned to them the first conception of transfusion. He was, however, announcing an advance in technique by stating his idea of transfusing blood from one species of animal to another species—calf to dog—and finally, in logical sequence, from an animal to man. He then told how he actually carried this out as a therapeutic operation. On 15 July 1667 he had noticed a youth of 15 or 16 who had suffered 20 bleedings for "a contumacious and virulent fever, in order to assuage the excessive heat. Before this disease, he was not observed to be of a lumpish dull spirit, his memory was happy enough, and he seemed chearful and nimble enough in body; but since the violence of this fever, his wit seemed wholly sunk, his memory perfectly lost, and his body so heavy and drowsie that he was not fit for any thing. I beheld him fall asleep as he sate at dinner, as he was eating his Breakfast, and in all occurrences where men seem most unlikely to sleep. If he went to bed at nine of the clock in the Evening, he

(489) *Num. 17.*
A LETTER

Concerning a new way of curing sundry diseases by Transfusion of Blood, Written to Monsieur de MONTMOR, Counsellor to the French King, and Master of Requests.

By J. DENIS Professor of Philosophy, and the Mathematicks.

Munday July 22. 1667.

SIR,

THE project of causing the Blood of a healthy animal to passe into the veins of one diseased, having been conceived about ten years ago, in the illustrious Society of *Virtuosi* which assembles at your house, and your goodness having received M. Emmery, & my self, very favorably at such times as we have presum'd to entertain you either with discourse concerning it, or the sight of some not inconsiderable effects of it: You will not think it strange that I now take the liberty of troubling you with this Letter, and design to inform you fully of what purposes and successes we have made in this Operation; wherein you are justly intitled to a greater share than in any other, considering that it was first spoken of in your *Academy*, & that the Publick is beholding to you for this as well as for many other discoveries, for the benefits & advantages it shall reap from the same. But that I may give you the reasons of our procedure & con-

Ccc

vince

on 25 June 1667 to Monsieur de Montmor, Counsellor to the King. The letter was set up in type to be issued as No. 27 of the *Transactions* dated "Munday July 22. 1667," but it was suppressed before general publication. The issue numbered 27 actually published was dated "Munday, Septem. 1667" for the months of July, August, and September. The number begins with "An Advertisement concerning the Invention of the Transfusion of Blood," in which the editor, Henry Oldenburg, explained that he was "returning to his former exercises which by an extraordinary accident he was necessitated to interrupt for some months past." The "extraordinary accident" was in fact his confinement in the Tower of London on suspicion of spying for a foreign

needed to be awakened several times before he could be got to rise by nine the next morning, and he passed the rest of the day in an incredible stupidity."

Denis attributed this state of affairs to loss of blood rather than to the fever. He accordingly bled the boy of 3 ounces (86 g.) and transfused about 9 ounces (255 g.) into his arm from the carotid of a lamb. The boy felt a burning along his arm, but had no other symptoms and quickly recovered from his drowsiness, becoming as nimble as before and putting on weight. Encouraged by this result, Denis tried another transfusion on a man of 45 "having no considerable indisposition"—in fact the experiment had little justification. The man was bled 10 ounces (283 g.) and was given 20 (567 g.) in exchange from a lamb. He had the same pain along his arm as the first patient, but felt stronger than before and cheerfully slaughtered and flayed the donor lamb, being a butcher by profession. Later Denis performed further transfusions, and one patient, suffering from "an inveterate phrenzy," showed every sign of having received a considerable amount of incompatible blood, exhibiting pain in the arm, a rapid and irregular pulse, sweating, pain in the back, vomiting, diarrhoea, and finally passing urine almost black with haemoglobin.

The best the London *virtuosi* could do was to publish in the *Transactions* for 21 October 1667 part of a letter from Dr. Edmund King describing his *preparations* for transfusing a man from an animal, though the experiment had not actually been done. It was not until 23 November of that year that Arthur Coga, an indigent Bachelor of Divinity of Cambridge, was transfused with lamb's blood by Drs. Lower and King at Arundel House. He suffered no inconvenience and asked for a second transfusion, no doubt in return for a

suitable reward. Samuel Pepys witnessed both the early experiments and the first one done on a man, making many pleasant quips about it in his diary.

It is clear that, though London had priority for the initiation of the preliminary transfusion experiments, Paris could justly claim it for the therapeutic operation on a human being. Even when London first transfused a man, it was purely experimental, not therapeutic. So let us hand the laurel to Paris in this, the tercentenary, year—though we must also record that the value of this priority was soon to be sadly discounted. Denis published five more pamphlets in 1667 and 1668, but in the latter year one of his patients died after three transfusions, and proceedings against the doctor were instituted by the widow. When brought to trial Denis was exonerated, the patient's death having been proved to be due to arsenic administered by his wife. Nevertheless a law was introduced forbidding the performance of any transfusion without the permission of the Faculty of Medicine of Paris. The Faculty was in any case strongly opposed to the whole idea and the practice of transfusion from animals was quite rightly abandoned. In London, too, no account of the second transfusion given to Coga was ever published, since the affair was bringing ridicule and discredit on the Royal Society. Indeed, little further was heard of blood transfusion for more than a hundred years. A tercentenary likely to elicit more enthusiasm will not be due until the year 2118. It was on 22 December 1818 that James Blundell, obstetrician to Guy's and St. Thomas's Hospitals, described in a paper delivered to the Medico-Chirurgical Society the first blood transfusion from *man-to-man*, performed with the help of a surgeon, Henry Cline. That was the true beginning of modern therapeutic transfusion.

CONTEMPORARY THEMES

Some Weaknesses in Hospital Service Organization

GEORGE DISCOMBE,* M.D., B.S.C., F.C.PATH., F.R.I.C.

Brit. med. J., 1967, 4, 411-413

It is now clear that no appeals or protests are likely to produce a big increase in the money allotted to the National Health Service. This is a political decision taken because taxation is already heavy, and all Government spending must be kept within the bounds of practicable taxation. Cries to "Take the N.H.S. out of politics" are futile; though everybody wishes to provide excellent medical care, the cost—over £1,500m., or over £30 for every man, woman, and child in the country—can be provided only by the Government out of taxation, which must always be a political matter.

Waiting-lists

The waiting-list for admission to hospital remains steadily at about half a million—about four weeks' admissions; but since in many hospitals half or more of admissions are emergencies the delay for elective admissions may be several months, so that a patient with a simple hernia or with varicose veins may wait for several months. A reduction in stay of only one day for each patient would increase the throughput of the N.H.S. hospitals by about 300,000 each year, and presumably reduce the waiting-list.

The reasons for waiting-lists, like their size, vary from region to region, from hospital to hospital, and from department to department. About 15% of hospital beds for acute cases are occupied by long-stay patients, many of whom are suitable for local authority geriatric homes, were there enough of them; but these again have to be provided for out of taxation. In my own hospital some specialist waiting-lists are inflated because many of those on them have been offered admission but have asked for a delay, thus wasting one or two bed-days. Those who refuse are usually women who cannot arrange for their young families to be looked after during their absence. Closer co-operation between hospital admission officers and local authority social services might reduce these difficulties. Some waiting patients need investigations which could be done while they were outpatients were a day ward available, or radiological or laboratory facilities improved, or, what may be equally important, if sufficient specialist time was available for cystoscopy, gastroscopy, and the like.

In some hospitals the limit to surgical admissions is the time available in operating-theatres. I have heard one surgeon complain that within a month two of his patients had died while he was waiting for an operating-theatre to become available. Registrars complain to me that patients are avoidably detained in hospital to await specialized radiological or

* Pathologist, Central Middlesex Hospital, London N.W.10.

biochemical investigation. During the past few years I have visited several laboratories to study their needs, and repeatedly found that within the space available at present each needed to spend £4,000 to £6,000 to make the laboratory reasonably effective—quite apart from needing more building because they were grossly overcrowded. In these hospitals, as in my own, inadequate laboratory services are a considerable check on patient throughput. In some hospitals this check can be removed by improvements in equipment, though others need more buildings or more staff. Since the demand for biochemical investigations doubles every five or six years, the laboratory will increasingly limit the throughput of a hospital.

Limits to Throughput

Thus the factors which limit throughput are often not a lack of beds but lack of operating-theatres and of radiological or laboratory facilities. We do not know for how many hospitals this is true; but in such hospitals it is much cheaper to improve these facilities than to provide more beds, which in such cases would not affect throughput and yet would demand more nurses, thus uselessly increasing the cost of treatment.

Most hospitals would benefit from an analysis of the factors which limit throughput; in many cases the different clinical units would be affected differently by single specific changes—thus the gastroenterologists may need more laboratory and radiological investigation and the surgeons more theatre time or radiological services. Some sort of analysis of social effectiveness is also needed so as to evaluate the importance to families and to the body politic of clinical advances; for example, an intensive coronary care unit may cut the early death rate by 20% but produce semi-invalids of limited or zero ability to work. Such analyses and comparisons are notoriously difficult, but might indicate directions in which expenditure would be most effective.

Operating-theatres, laboratory facilities, radiological departments, day wards are not cheap to provide, because they usually require new buildings; but within each building there are individual items of equipment that are much less expensive—air-conditioning or operating-tables for the theatre, auto-analysers or data-processing equipment for the laboratory, image-intensifiers or developing units for the radiological department. Such individual items cost £500 to £5,000—0.025 to 0.25% of the annual expenditure of a hospital but 10 to 100% of the money available for all innovations. An increase in revenue of 1% might produce enough to bring considerable improvements to the services available by making it possible to purchase modern equipment.

How can individual hospitals obtain such an increase without recourse to taxation? There are three possibilities—the encouragement of private beds within the hospital service, the encouragement of charitable gifts through the Leagues of Friends, and the imposition of direct charges. This last is very much a political problem, so that here I will confine myself to the former two.

Private Beds

A system where private practice continued separately from and independently of the N.H.S. would inevitably lead to a division of the profession into two groups. The founding fathers of the N.H.S. hoped to overcome this danger by establishing part-time hospital appointments for senior men ("consultants") and by paying salaries sufficient to provide an income comparable to those which could be obtained in private practice. We are now faced with a situation in which an increasing proportion of the middle class are paying insurance premiums in order to obtain the facilities of private attention, oblivious to the fact that outside the N.H.S. are few hospitals with the facilities required for all modern medical

services. Whereas in my hospital a surgeon can, if it be essential, organize an emergency blood transfusion within minutes, and at my outlying hospitals within an hour, the delay in most private hospitals and nursing-homes is far greater, so that in the few cases of unexpected emergency in private hospitals to which I have been called I have preferred to transfer the patient to an N.H.S. hospital—a course adopted by many others.

The facilities which can be obtained in private practice are few, but they are important to many middle-class patients. Among them are privacy, some choice in the time of admission or at least advance warning, and the assurance of the personal attention of the chosen consultant. The importance of privacy can be overstressed—indeed, it is most important for patients whose illness is not severe, such as the business executive recovering from an elective operation. Advance warning of the time of admission is very important to those with managerial responsibilities, whether in office, factory, or home (the housewife is a manager and frequently refuses admission when offered because of the difficulties of running her home). Assurance of personal attention is said to be the backbone of the system of personal doctoring, though I confess that in hospital today the individual consultant is becoming submerged in his team.

There seems to be a choice of two courses: to have two distinct services, clearly separate, one marked "private," the other marked "N.H.S.," or to have a choice within the N.H.S. between two categories of service—the one very much as it is today for most of the population, the other a "private" service providing greater privacy and facilities for such business or social activity as is possible, a reasonable choice in the time of admission, and the certainty of the attention of the consultant of choice and his team.

The cost of private beds anywhere is upwards of £7 daily, the average cost of any N.H.S. bed. At present many large hospitals have no private beds, others barely 1% of their total; many less well equipped small hospitals have 2 to 3%. These proportions could with advantage be reversed: if a 75% bed occupancy were secured for private beds numbering 2% of the total beds in a hospital, then the contribution of 1.5% to the hospital's expenditure would make a considerable difference to the facilities available, and if it resulted in improvements to the services which were limiting throughput it might well result in an increase in the patient-turnover of the hospital as a whole. This assumes, of course, that the receipts from private beds would remain with the hospital group and not be remitted to the Exchequer as is the present practice.

Treasury's Accounting System

The standard accounting system is no doubt admirable for administrative departments; but it is not so admirable for service departments like the N.H.S. in which changes are often needed at short notice. To insist that underspending in one section of accounts may not be set off against overspending in another seems absurd when a capital investment of £2,000 may produce a revenue saving of £800 a year. To insist that sums received by a hospital management committee shall be returned to the Treasury rather than be retained by the committee discourages those officers who are concerned with the collection of such dues, whereas if these receipts were available as extra money for the hospital management committee there would be a direct incentive for the officers to collect every possible penny. No hospital management committee is encouraged to save when any "underspending" is returned to the Treasury at the end of the financial year; but if saving from year to year were permitted (especially of the small sums allowed for "innovations") great care would be exercised in the choice of equipment, contrasting with the present hectic spending spree which starts in February when

the treasurers of regional hospital boards and hospital management committees discover that they may have a surplus.

League of Friends and Charity

From the inception of the N.H.S. it has been policy to prevent hospital administrators soliciting gifts to their hospitals. The reasons are many, but the most important was to break down the idea that the N.H.S. was a charity instead of a service provided by taxpayers for themselves and their dependants to use as a right; and I, for one, think that this break with mediaeval tradition was right and necessary. But now, after 20 years' work, the idea of the N.H.S. as a "charity" must be dead except among the most elderly and those who will never accept any change. Local patriotism is still active.

Most people are benevolent and find the chance of exercising benevolence pleasurable. Until the last war hospitals were the most important object of benevolence, and an organization such as that of the Freemasons supported equally education, the care of the aged, and hospital care. What the Freemasons realize, and what most of the population have not discovered, is that all these establishments need to be maintained. It is comparatively easy to persuade people to give money for bricks and mortar, which they can see and take pride in; it is much more difficult to persuade them to pay for porters, domestic orderlies, postage, and mechanical aids to cleaning. Their consciousness of having exercised benevolence seems to make them expect others to exercise benevolence by giving their services free; yet administrators know that the annual maintenance of a unit such as a pathology laboratory may equal or exceed the initial capital expenditure on building and services.

The conclusion is therefore that if we are to encourage people to give to their local hospital the gifts should be used to buy equipment which demands the minimum of revenue expenditure. Building and general planning must remain the prerogative of the regional hospital board and hospital management committee; but much of a department's equipment, and certainly replacements for old and obsolete equipment, could be given by the public. Yet these are the very things of

which the public can have little or no knowledge unless it receives specific instruction.

Such specific instruction should not be the prerogative of individual consultants trying to build up a department, because when this happens other parts of the hospital—for example, radiology and clinical laboratories—may be overloaded. Further, it should be organized on a group basis, rather than for individual hospitals, partly to minimize jealousy between hospitals and partly to make sure that large gifts are not devoted to hospitals unable to use them effectively and efficiently. It seems reasonable for hospital needs to be analysed by the group medical advisory committee, and the order of precedence and sums required communicated to the lay organization through the hospital management committee mechanism, preferably by the group secretary or his deputy, who will be able to advise the group medical advisory committee about possible future changes in organization.

Conclusion

From the point of view of national finance these suggestions seem harmless. They require no increase in taxation. They would divert income, after taxation, away from personal expenditure into a field which is notably short of money, and much of this income would be spent on the purchase of scientific equipment, most of which home industry is able to supply. It is generally considered that a flourishing and stable home market is a necessary condition for satisfactory exports, so that the changes I have suggested might even improve the balance of payments.

There is a strong and universal emotion that wealth should not control access to medical facilities—a feeling which to a large extent I share; but if wealthy people wish to pay so that more attention is given to their convenience and comfort than can be provided by the N.H.S. for the general run of the population, then surely it is better for this desire to be satisfied within the N.H.S. than outside it. This would be valuable if the money thus received were retained in the hospital group and devoted to improving local facilities. I am satisfied that in some hospitals this would actually increase the number of patients treated in "non-private" beds rather than reduce them.

CONFERENCES AND MEETINGS

Clinical Electroencephalography in Childhood

[FROM A SPECIAL CORRESPONDENT]

A symposium on electroencephalography in childhood was held in Gothenburg in Sweden in August. There was a wide range of topics, from studies on young animals to clinical investigations on children, and, in addition, advanced apparatus was discussed.

Dr. N. MONOD and Dr. P. DUCAS (Paris) discussed the prognostic value of the electroencephalogram (E.E.G.) in the first two years of life of a child. A grossly abnormal E.E.G. in full-term or premature newborn babies was related to an unfavourable clinical evolution in 95% of the cases. An exception to this trend was represented by mongolism and kernicterus, where in spite of the severe clinical sequelae the E.E.G. abnormalities in the neonatal period were minimal. Dr. C. DREYFUS-BRISAC and A. MINKOVSKY (Paris) had studied the E.E.G. of 96 "small for dates" newborn babies. The assessment of

gestational age could be correctly made (within two weeks) in 73 babies who were in reasonable general conditions (out of a total of 96 babies). Dr. Dreyfus-Brisac had been able to recognize differences in the E.E.G. features between true prematures (born before 37 weeks) and "small for dates" newborn babies in 90% of the cases.

The host of the conference, Professor INGEMAR PETERSEN (Gothenburg), reported with his co-workers Dr. EEG-OLOFSSON and Dr. SELLDEN on the occurrence of paroxysmal activity in the E.E.G. of normal children. They had found that out of 1,000 normal children some form of paroxysmal activity in the E.E.G. occurred in 99. When this figure was broken down, however, 38 children showed only abnormal responses to photic stimulation, while a further group of 36 children showed only paroxysmal discharges

during sleep. These workers had found that the amount of paroxysmal phenomena in the E.E.G. was significantly greater in girls than in boys. The prognostic importance and the correct evaluation of these abnormal E.E.G. features in apparently normal children could not be fully appreciated without a very long-term follow-up.

Localization Technique

Some of the papers dealt with applications of special techniques to particular problems. Among these Dr. BECHTEREVA (Leningrad) reviewed special techniques for the localization of lesions, and Dr. W. A. COBB (London) was able to record peculiar phenomena from the depth of the brain in one patient with subacute sclerosing leukoencephalitis.

Among the clinically orientated papers Dr. G. PAMPIGLIONE and M. LEHOVSKY (London) presented a follow-up study on a group of 24 children with histologically proved neuronal lipidosis (eight with Tay-Sachs disease and 16 with so-called amaurotic family idiocy). In the group of children in whom the symptoms began between the age of 2 and 4½ years there was a peculiar combination of E.E.G. features even at an early

stage of the disease, which was not seen in patients with other diseases in this age group. The peculiar neurophysiological findings (both E.E.G. and polyelectromyographic studies) were demonstrated in children of similar age groups but at different stages in the course of individual illness. It was clear that the current classification of the neuronal lipidoses was inadequate.

Dr. A. G. Z. ZEMSKAYA (Leningrad)

presented her results of surgical treatment in over 100 children with epilepsy. Direct recording from the exposed brain and direct stimulation of the cortex had helped her a great deal in the surgical treatment of children with focal epilepsy. In particular direct recording had been found valuable not only as a localizing tool during cortical excisions but also as a basis for stage-by-stage removal of the epileptogenic focus.

Disabilities in Middle-age

[FROM A SPECIAL CORRESPONDENT]

The fourth biennial Chelmsford symposium, organized jointly by the Mid-Essex Division of the B.M.A. and the Chelmsford Medical Society, was held at Broomfield Hospital on 28 and 29 October, and dealt with "Disabilities in Middle-Age."

In a review of "The Factors Influencing Disease in the Middle-Aged" Sir JOHN RICHARDSON (London) drew attention to the rising figures of absence from work through sickness in Britain. Since the war the rate had doubled and for some occupations at least this was particularly true of the younger age groups. This, he suggested, might reflect a new attitude to going sick, which was now socially and economically more acceptable. If, when these younger employees became middle-aged themselves, they carried this pattern with them, the rise in sickness rates would accelerate. Comparative international statistics showed an inverse ratio between sickness rates and unemployment rates, even though death rates differed little from country to country. There was also much evidence that with responsibility and rank sickness rates fell.

The partially successful, who had reached their peak of attainment, but who could not accept that future advancement was unlikely, might retreat into illness in middle-age if the opportunity offered. There were others who had gone too far for their capacities and who became anxious or depressed because of the stress involved in keeping up the pace. The ruthlessly successful often hid self-doubt and might unconsciously exaggerate their physical handicaps to escape the pressure, or might develop psychiatric difficulties. The too successful risked ignoring the early symptoms of organic diseases, especially those arising from stress. Concluding, Sir John quoted evidence that in later middle life a man off work for many months might never return to work at all. Not only was it important to appreciate the seriousness of disease in this age group, but it must be remembered that this was often due as much to modes of life and social pressures as to primary organic pathology.

Carpal Tunnel Syndrome

Dr. F. LEES (Chelmsford) showed that little could be added even now to the descriptions given by many physicians in the nineteenth century of what McArdle in 1949 had named the carpal tunnel syndrome. He stressed that abnormal neurological signs were often absent in those patients with most disturbing symptoms and believed that the diagnosis should be made on the history alone, supported sometimes by therapeutic

trial with diuretics, corticosteroids, or splints, and very occasionally by nerve-conduction tests. The simplicity of the operative treatment of the syndrome was demonstrated by Mr. BRUCE PENDER (Chelmsford).

Mr. B. W. BROADHURST (Southend) felt that very few of the middle-aged patients who presented with lumbar spine and root pains were suffering from true prolapse of an intervertebral disc. For those who were he considered that surgical excision of the disc was the only satisfactory form of treatment. The majority of middle-aged patients with this syndrome were suffering from multiple disc degeneration with narrowing and deformity of the disc spaces on x-ray examination. This group of patients could be helped by the usual conservative methods, such as manipulation, surgical supports, physiotherapy, and bed boards. Nevertheless, in probably two-thirds of patients with low back pain psychogenic factors were important in causation, and correction of social and economic difficulties could be curative.

In a survey of osteoarthritis Dr. J. T. SCOTT (London) pointed out that a field study had shown that this condition accounted for one-quarter of the rheumatic complaints affecting an urban population. The chemical basis for the primary degenerative changes in the joint cartilage was not understood. There was often a discrepancy between the severity of the pain and the extent of the pathological changes, and the importance of assessing the influence of emotional factors on an individual patient's symptoms was agreed by speakers during the subsequent discussion. The appearance of symptoms, or a rapid deterioration in the symptoms, of osteoarthritis might indicate the development of a depressive state.

Rheumatoid Disease

Professor E. G. L. BYWATERS (London) said that the discovery of the cause of any form of chronic inflammatory polyarthritis would provide the aetiological explanation of them all. Dealing in details with "rheumatoid disease," which he regarded as a multifocal systemic disorder, he indicated one clue to aetiology in the predilection of the disease for tissues affected by, and specialized for, movement. One illustration of this was the relative freedom from nodule formation of single limbs immobile because of severe joint disease or coincident hemiplegia. It appeared probable that rheumatoid disease was an autoimmune disorder; movement, particularly of inflamed tissue, produced an antigen, and the subsequent tissue reaction

induced further joint damage. Rheumatoid lesions in synovial and other soft tissues were reversible, but those affecting bones were not. The proportion of the population whose serum contained rheumatoid factor increased with age, but most did not have rheumatoid arthritis. The most severe types of the disease occurred independently of the presence or absence of a positive rheumatoid factor test.

Analysing some of the evidence for the presence of a strong genetic factor in the aetiology of rheumatoid disease, Dr. W. WATSON BUCHANAN (Glasgow) concluded that the genetic influence was small. Until some biochemical-marker of this genetic influence was identified epidemiological research of this type was unlikely to be of much value.

The cardiac lesions of rheumatoid disease were described by Professor T. B. COUNIHAN (Dublin). Histologically, the pericardium was involved more than twice as often as the endocardium or myocardium, while there was often disease of the proximal aorta. Clinically, evidence of such cardiac involvement was uncommon, and even then could in some cases be due to concurrent rheumatic fever. The commonest valvular lesion was aortic incompetence, but signs of severe haemodynamic disturbance were infrequent. Congestive failure was very rare, perhaps because the pathological changes were rarely severe until late in the disease, when mobility was very limited.

Dr. R. M. MASON (London) reported a double blind controlled trial of prayer in the treatment of rheumatoid arthritis. Analysis by the sequential method showed no significant difference between the treated and the control groups. In his experience, of every 20 cases of rheumatoid disease seen in hospital practice roughly five had a complete cure, five were cured with only minimal residual damage, eight required continued treatment, and one or two were very severely disabled. He found it very difficult to predict into which group any patient would fall. The principles of treatment were to modify the patient's disease, to modify the environment, and to obtain by explanation the co-operation of the patient and his relatives in these attempts. He believed that most of the common drugs for rheumatoid arthritis were, in the doses usually employed, analgesic rather than anti-inflammatory. He regarded aspirin as the simplest and safest. A preliminary pilot study of azathioprine (Imuran) in nine patients with rheumatoid disease of potentially disastrous severity had enabled the dosage of corticosteroids to be reduced in four and had led to the disappearance of arteritic lesions in three of four cases. Although severe toxic

effects had occurred in half the cases the results were sufficiently encouraging to justify a double blind trial of immunosuppressive therapy, which had now started. Dr. Mason was asked at what stage in the disease should corticosteroid therapy be introduced. He suggested it was often possible to identify a situation when the inflammation had settled to a degree which could be controlled by relatively small doses of corticosteroid and when structural damage was not yet extensive.

Sexual Problems

Patients had to be persuaded that the menopause was a change in life and not the end of life, said Mr. D. B. BROWN (Chelmsford). Explanation of how to adjust to the few physiological and the many psychological problems of this age was usually all that was required. If simple advice, aspirin, and sedatives failed to relieve the distress of the menopausal flushes, oestrogens should be given for several months, rather than for a few weeks. Advice should also be given on the use of vaginal lubricants during coitus, and on contraception. Up to the age of 45, Mr. Brown favoured the use of the contraceptive pill, but an intrauterine device was very suit-

able for those older than this, in whom its lesser efficiency was counterbalanced by less frequent ovulation.

Mr. R. H. BOYD (Chelmsford) said that impotence in middle-age required more careful assessment than in younger men, in whom it was almost always psychogenic. Interruption of established rhythms of sexual activity was a frequent cause of sexual difficulty. Physical causes included frontal and pituitary tumours, pernicious anaemia, local ischaemia, and, above all, diabetes. So far as psychological factors were concerned, reasons included wives with faded attractions and increased libidos, and the tendency of accountants and business men to go to bed with the wrong sort of figures. He believed a wise attitude to the inevitable effects of age was shown by a countryman of his acquaintance who after marrying a much younger woman as his second wife, said: "It may take longer, sir, but I don't grudge it time."

The final lecture of the meeting was given by Professor Sir EDWARD WAYNE (Gloucestershire), who spoke on retirement. This was an important subject when it was remembered that the expectation of life for a man aged 65 was now 13 years and for a woman aged 60 was 21 years, and that one in seven of the population were above the

usual ages of retirement. This was a problem particularly for the present generation of middle-aged people, who had been brought up with the view that work was a social responsibility and, having had experience of the Depression, might fear that retirement differed little from unemployment. The problem, which was really one of disengaging without undue psychological or financial deprivation, varied in pattern with the social class. For the worker one of the greatest stresses might be the loss of companionship with associates at his job, which now so often involved close team-work. Sometimes retirement was a relief to the man, but was a great strain to his wife, who now had her husband at home all day.

For the professional man, Sir Edward felt that it was wise to beware of retiring to the district with happy memories of sunny holidays, to live near—but not with—close relatives or friends, to remember that the chance of illness of one or other spouse was high (therefore avoid a large house with a large garden, far from the shops), and to be prepared to face the death of a partner. If financially possible, there was much to be said for retirement two or three years earlier than was officially enforced, to allow more time for the achievement of one's plans.

NEW APPLIANCES

New Bone Needle

Mr. B. HELAL, consulting orthopaedic surgeon, Chase Farm Hospital, Enfield, writes: A bone needle was designed to facilitate research into the intraosseous venous circulation. One of these needles is still in use after five years. It has been introduced into bone more than a hundred times.

The needle consists of a 6-in. (15-cm.)

cannula, 5/32 in. (4 mm.) in diameter, into which can be locked a trocar which has a large handle at its proximal end (Fig. 1). These together form at the point of the needle a self-tapping screw, 1 in. (2.5 cm.) in length. The needle is inserted by making a 3/4-in. (6-mm.) stab wound through the skin. It can then be introduced through the cortex of any bone (Fig. 2). Once the screw has

bitten into the bone no force is required to advance the needle.

It can be used to withdraw blood or marrow from the medullary bone or to introduce radio-opaque dye to outline bone sinusoids or the deep veins of the limb. The screw end of the needle helps to prevent any leak back of dye. At any time the trocar can be withdrawn and the needle advanced to pick up a core of bone for biopsy. When connected to a manometer it has been used to take direct measurements of marrow pressures.

In summary, its advantages are its strength, which is a guard against accidental breakage in the bone, and the large bore of the cannula through which bone contents can be aspirated with ease and radio-opaque dye introduced without difficulty, the screw end helping to prevent leak back of the dye. Its large handle allows it to be manually introduced with great ease, and once the screw has taken hold no force is required to advance the needle, so that accidental overpenetration is avoided. It appears to be popular with my general surgical colleagues for transosseous venography.

This needle is being made by the London Splint Company.

I am indebted to Mr. H. R. Vincent, instrument curator at Chase Farm Hospital, Enfield, for making the prototype for me.

Deaths from Tuberculosis

SIR,—Despite current optimism, many patients in Britain suffering from tuberculosis die unnecessarily and avoidably. During the past few years cultures from patients with organisms resistant to one or more of the standard antituberculosis drugs (streptomycin, P.A.S., and isoniazid) have been sent to a central register for these cases. By 31 December 1965, out of 1,257 patients with cultures resistant to all three drugs, 33% had died and 23% had obtained negative sputum.¹ Among the 1,170 patients whose cultures were resistant to only two of the standard drugs the results were scarcely better.¹ These figures are appalling and the public health danger obvious.

Using the "reserve" or second-line drugs available, several studies have shown that the sputum can be rendered negative in 80–95% of patients whose cultures were resistant to the three standard drugs^{2–5}; during observation for periods up to five years afterwards few patients have relapsed. These results have been obtained in centres where physicians have taken particular interest in such problems. The patients themselves are often unenthusiastic, uncooperative, persistent self-dischargers, drunks, or psychopaths; the drugs are frequently unpleasant and need careful control for toxicity; and the possible combinations of drugs need precise and

critical appraisal, with the help of expert bacteriological studies. Much experience, time, patience, and persistence are required.

Treatment will often fail when undertaken in centres with comparatively little experience of these problems. This was shown during a co-operative study in a number of centres in 1963, when 103 out of 117 patients given "reserve" drugs failed to complete 12 months of treatment.⁶ Three years later the results seem little better.

Surely, Sir, patients suffering from drug-resistant tuberculosis should be treated in special centres, as others have advocated.^{7,8} Otherwise the present disturbingly low cure and high death rates will continue.—I am, etc.,

Ware Park Hospital,
Ware, Herts.

"Big Spleen" Disease

SIR,—The article by Dr. P. J. S. Hamilton and others (30 September, p. 823) and the one by Dr. D. S. Pryor (same issue, p. 825) advocating splenectomy should not go unchallenged. In both papers it is suggested that in areas where malaria is endemic this infection may be responsible for some cases of massive splenomegaly. Our experience in Ibadan, Nigeria, is that the majority of patients in whom there is no evidence of other disease respond well to continuous suppressive therapy with proguanil 100 mg. daily. After a year's treatment their anaemia is corrected, the spleen is considerably reduced in size, and there is a great improvement in body weight and well-being. The relationship is obscure, as these patients have neither overt clinical malaria nor an increased parasitaemia; we think the mechanism is rather one of an abnormal immune response to repeated infection. Our results of continuous treatment for three to five years in 40 patients will shortly be published.

Dr. Hamilton and his colleagues discuss the dangers of splenectomy, but had little trouble in their seven cases. On the other hand, Dr. Pryor had one immediate and two late deaths in his group of 15 splenectomies

(an overall mortality of 20%). Others¹ have reported a similar high mortality, and our experience that death from cerebral malaria occurred in a person who before splenectomy had an apparent high resistance is supported by the finding of reduced resistance after splenectomy in chimpanzees.²

Our purpose here is to suggest that continuous malarial suppression therapy should be the treatment of choice in unexplained splenomegaly in malarious areas. Splenectomy should be considered only when at least one year's treatment has been ineffective.—We are, etc.,

North America Interview Board

SIR,—Dr. C. C. M. Watson (14 October, p. 114), referred to the campaign to coax emigrant doctors to return to Britain. May I relate my experience of the recruiting team that toured America?

On 11 October I received a circular letter from the British Post in Edmonton informing me that the team would be in Banff on 14 and 15 October, and in Calgary on 16 and 17 October. If I wished to interview them, would I please phone the Post for an appointment. This I did, to be told to phone the team direct. An evening phone call to Banff failed to find any of the team available. On 16 October I was in Calgary and went to the hotel where the team was in residence. A phone call from the foyer to a suite above was answered by a deputy—"What is your specialty?" On being told general practice, the interest ceased and no interview could be arranged before 5.30 p.m., and only then if I was definitely interested in returning to Britain.

Having been in general practice in Britain for 16 years I feel I gave the National Health Service a fair trial, hoping year by year that conditions would improve. I was keen to know if the conditions had changed for the better, and if so in what way. These questions remain unanswered, and the only conclusion I can draw is that the answers would not have been favourable. We emigrants await with interest the report of the team's work.—I am, etc.,

J. STANNERS.

Medical Centre,
Daysland, Alberta,
Canada.

SIR,—On 12 October I received a letter from the British Government Office in Edmonton notifying me that the British Ministry of Health board would be in Banff on the next two days, that is to say 13 and 14 October, and in Calgary on 15 and 16 October. The letter stated that the aim of the doctors' extensive North American tour "is to meet those doctors (with whom they have already established contact), who, as U.K. citizens, qualified in Britain and are now considering returning to that country to work." The letter continued: "They have not asked my assistance in that principal object, but they have asked me to 'pass the word around' that they would also be glad to have a chat and an exchange of views with any doctor (and his wife) in the above British category who would like to meet them—even though he has not the slightest intention of returning to Britain to practise."

Several questions arise from this letter: Why did not this board contact the British doctors in Alberta instead of leaving it to the Trade Commissioner to do so at the last minute?

Why was not adequate time given for the recipients to act?

Why should they meet in Banff, a town with a population of 3,000 people with nine doctors, only two of whom are British? Why not Edmonton, the provincial capital, 250 miles away, a city of 360,000 with many

British doctors, a teaching hospital, and several British residents who are not yet on the *Register*?

Surely the committee, had it taken the job at all seriously, would have visited Edmonton in central Alberta. As it was it moved 77 miles from Banff to Calgary on the only road out of the resort (other than the one to Jasper, which is 180 miles to the north and which has two British doctors). If this committee had been interested in discussing the whys and wherefores of immigration or re-immigration of doctors in Alberta it would have made more effort to contact us.

In short, Sir, we bring the activity of this committee (or lack of it) to your notice because we do not feel that it is getting as much information as could have been acquired by a carefully worded questionnaire. Also the poor geographical location, in Alberta at any rate, and the complete indifference in contacting people, would seem to us to suggest this expedition is little more than "window dressing" on the part of the Ministry of Health, and a very pleasant trip by the committee at the British taxpayers' expense.—We are, etc.,

C. D. ELTON.

Acrylamide Poisoning

SIR,—In view of the recent paper by Drs. T. O. Garland and M. W. H. Patterson (21 October, p. 134) we feel we should report the preliminary results of a study of acrylamide neuropathy in baboons. Acrylamide was shown by D. D. McCollister and his colleagues¹ to be toxic to a variety of experimental animals, including monkeys, but pathological changes in the nervous system were not demonstrated. Only in rats, subsequently studied by P. M. Fullerton and J. M. Barnes,² has it been established that there is a toxic degeneration of the peripheral nerves. From the present work it is now clear that peripheral nerve degeneration also occurs in primates.

Six adult baboons (*Papio hamadryas*) were given acrylamide by mouth in a daily dose of 10–15 mg./kg. After six weeks the animals began to show mild weakness of the lower limbs. After eight weeks some clumsiness of the hands was noticeable, and the animals began to lose their normal cry. By 12–15 weeks there was severe bilateral weakness affecting the facial muscles and the muscles of mastication as well as the muscles of the limbs. Ataxia was usually so severe that an animal could sit upright in the cage only by propping itself up with its arms. At this stage the tendon reflexes were absent. Appreciation of pinprick in the hands and feet was never completely abolished, but some loss of tactile and joint sensation may be inferred from the fact that animals would drop objects from the hands without being aware of it. Sphincter disturbance of the type described in rats poisoned by acrylamide was not seen.

Electromyography confirmed the presence of widespread denervation in the distal muscles of the limbs. Maximal motor conduction velocity in the median nerve was reduced by 30 to 40%, and sensory action potentials from the fingers disappeared as the disease progressed.

Pathological studies have confirmed the presence of extensive peripheral nerve de-

generation involving both motor and sensory nerves, and affecting particularly the distal parts of the longest nerve fibres. Damage to the recurrent laryngeal nerves was conspicuous in all animals. While the pathological changes were mainly of the Wallerian type, occasional segmental demyelination was present and changes in paranodal myelin were relatively common. The brains of affected animals have not yet been examined, but preliminary studies of three spinal cords and their dorsal root ganglia have not shown significant neuronal loss or demyelination of fibre tracts.

Two animals are still alive one year after stopping poisoning, and both have greatly improved clinically. Electromyography and nerve biopsy are being used to follow the time-course of peripheral nerve regeneration and remyelination in these animals.—We are, etc.,

Oral Contraceptives and Dental Care

SIR,—The hypertrophic gingivitis of pregnancy, which is thought to be due to hormonal changes, is also seen in the patient on the "pill." In dental practice it is normal to see the slightly puffy appearance of the gums and marginal soreness.¹ Lindhe and Björn² studied 115 women aged 18–35 who were taking oral contraceptives. They observed the same pattern of gum lesions which are reported by Orban.³ Following a study of 1,002 women Mohamed S. Gridly⁴ gave a full account of the gingival condition in pregnant women.

The dental problem is that the disordered arrangement of the delicate tissues round the necks of the teeth may progress to acute infection (Vincent's disease or trench mouth, now referred to as acute ulcerative gingivitis) or the changes may become chronic, leading to pyorrhoea. With proper oral hygiene and routine attention to diet the patient can usually prevent either of these conditions. Occasionally, the hypertrophy of the gum tissue leads to a tumour. This is benign and the epulis clears up when the menstrual cycle is re-established.

The proper care of the expectant mother is so important that this group of patients is given special priority by the National Health Service. They are given the same relief from statutory payments as children. Although I should not like to see the day when the question "Are you on the 'pill'?" is added to the dental estimates form (the existing footnote threatens persons who make false declarations with a fine not exceeding £100 or three months' imprisonment or both), I do now find myself looking for gingivitis in my young female patients.

There has been so much written about the side-effects of the oral contraceptive that I should like to have the opportunity to draw attention to the need for the pseudo-pregnant to take extra care of their teeth. The old wives' tale—"for every child a tooth"—has some truth, for, although the rate of dental caries may not increase severely, dental disease

becomes an acute problem in the neglected mouth. Interviewing 222 women who were attending the Queen Victoria Maternity Hospital at Adelaide, Fanning, Barrett, and Cellier found that of these 57% thought they had no trouble with their teeth or gums.⁵ In fact of this group of 125 patients 75 were in urgent need of treatment and 46 required treatment of a routine nature.

We should therefore add to our list of warnings given to the patient for whom oral contraceptives are prescribed that she will need regular dental care.—I am, etc.,

Psychotropic Drugs

SIR,—We should like to reply to the criticism of our views which has been expressed by Dr. P. J. Dally (28 October, p. 233), and to extend more constructively the discussion on the place of controlled trials of treatment in psychiatry. In his criticism Dr. Dally accuses us of confusing and oversimplifying the subject by failing to differentiate between endogenous depression and other psychiatric conditions. If he re-reads our letter (14 October, p. 108) he will see that we specifically excluded such confusion by pointing out that the M.R.C. trial,¹ which showed phenelzine to be valueless in endogenous depression ("depression as defined in the terms of that trial") must not be taken to show that phenelzine was necessarily valueless in other conditions.

However, the essential problem which interests us, and is of considerable importance to all psychiatrists and to doctors generally, is the problem of the satisfactory evaluation of psychotropic drugs, particularly the antidepressants. The British taxpayer is currently spending something approaching £5m. per annum on antidepressants, and it would seem reasonable to suggest, as has been done by the Dunlop Committee, that scientific evaluation should be attempted before this figure is further increased. Uncontrolled observations, even by experienced clinicians, are not really enough; we know that most depressions get better anyway, regardless of the treatment used. Various studies have found rapid marked improvement in up to 83% of non-psychotic depressive persons given placebo tablets. One wonders how much higher this percentage might become if the placebo were backed by the faith and enthusiasm of some therapists. When the non-specific sedative effect of phenelzine is added also the figure may well go up to 95% or more. We put forward this view, not in any offensive spirit, but as a serious argument in favour of the controls which we feel to be essential in this difficult field. It might be relevant also at this point to recall that claims for other treatment techniques in non-psychotic depression—for example, those often made by experienced psychotherapists—may equal the claims made for the drugs. Psychotherapy has been used for over half a century without really satisfactory evaluation. Are we going to drift into the same

appalling position with respect to drugs such as the monoamine oxidase inhibitors?

We would agree with Dr. Dally that it may not be easy to carry out controlled trials of the necessary high standard. Blackwell and Shepherd² have recently clearly illustrated some of the difficulties, and one of us has reviewed³ the chaotic state of affairs which is resulting from the publication of many drug trials which are not of sufficient technical quality. But it must be clearly understood that this present chaos is not to be used as an argument against controlled trials, but rather as an argument for the carrying out, in psychiatry particularly, of better controlled trials.

We agree with Dr. Dally that the Medical Research Council could help considerably to improve the present unsatisfactory position. While it was far from perfect, the M.R.C. trial was perhaps the most reliable of the antidepressant drug trials carried out in this country, and several features of its design seem to us to recommend themselves for future trials of treatment in other psychiatric conditions. It would be presumptuous to attempt to advise the Council on finance, but it is known that the drug companies spend considerable sums on the financing of small and often unsatisfactory trials which are carried out by doctors acting individually or in small independent groups. We feel that there are several important arguments to be advanced in favour of larger, multi-centre, and more impersonal trials such as those run by the M.R.C. Perhaps the drug companies and the Council could co-operate over this. Certainly something needs to be done.—We are, etc.,

Q Fever Endocarditis

SIR,—Cardiac involvement in Q fever has been recognized in a number of cases reported in recent years from Britain. Although these reports indicate a growing awareness of Q fever as a cause of endocarditis, there is often considerable delay in reaching the diagnosis. We here report another case, diagnosed after death, which illustrates the clinical and pathological features and poor prognosis of the disease.

In March 1964 the patient, a gardener 44 years of age, presented with a mild febrile illness and dry cough. His family doctor detected signs at the left base and pulmonary disease was confirmed radiologically. No radiological evidence of cardiac abnormality was present either at this time or four weeks later, when there was clinical and radiographic clearance of the lung lesion. Malaise, lethargy, and increasing dyspnoea persisted. The ankles became swollen and transient rash was noticed during this period. At the end of May, when next seen, his condition had deteriorated to the extent that cardiac failure was beyond doubt. He was afebrile at this time and showed mild icterus with purpuric rash on the thighs. There was clinical and radiological cardiomegaly with manifestations of aortic incompetence. Slight hepatosplenomegaly was de-

tected, and air entry was diminished at the right base.

There was mild hypochromic anaemia (Hb 12 g./100 ml), leucopenia (2,600/cu. mm.), with neutropenia (364/cu. mm.), and thrombocytopenia (70,000/cu. mm.). The anaemia remained at this level throughout the course of the illness but there was considerable fluctuation of the leucocyte count (700 to 12,000/cu. mm.) and of the platelet count (5,000–67,000/cu. mm.). Multiple blood cultures were taken and failed to establish a bacterial diagnosis. Serum bilirubin varied between 1.2 and 2.7 mg./100 ml, serum alkaline phosphatase was constant at 20 K.A. units, serum protein 6.8 g./100 ml, serum albumin 3.0 g./100 ml, and serum globulin 3.8 g./100 ml, with electrophoretic evidence of hypergammaglobulinaemia. The maximum blood urea was 54 mg./100 ml, and moderate albuminuria was constantly present.

Because of the severity of the disease, intensive antibacterial therapy (penicillins and streptomycin) was started immediately after the first series of blood cultures had been taken. Death occurred on 14 June after progressive deterioration.

Since the diagnosis of Q fever endocarditis was considered possible, precautions were taken to minimize the danger of infection of personnel concerned in the necropsy. This revealed bilateral pleural effusions, each of 800 ml., and bilateral bronchopneumonia. The heart weighed 490 g., all chambers being dilated. The aortic valve was distorted and calcified, and several friable vegetations arose from the fused cusps and adjacent aortic sinuses. Histological examination of the vegetations showed many microcolonies of haematoxyphil bodies. The peritoneal cavity contained almost 2 l. of clear bile-stained fluid, and the liver (1,980 g.) and the spleen (290 g.) showed chronic congestion. The presence of renal and splenic infarcts was confirmed histologically, but the rickettsia-like bodies were not identified in these organs. These findings were considered to be consistent with rickettsial endocarditis, and serological and cultural verification was sought.

Complement fixation tests of serum collected before death showed high titres of antibody to *Rickettsia burneti* antigens (1,024, Phase 1; 2,048, Phase 2), but none (<8) to epidemic typhus or psittacosis-group antigens. *R. burneti* was isolated from 10⁻⁴ dilution of approximately 10% suspension of heart valve by intraperitoneal inoculation of guinea-pigs—that is, at least 10⁵ I.D.₅₀ per gramme tissue.

It seems probable that Q fever caused the febrile illness with pneumonia in March 1964, and that endocarditis was established at that time. The subsequent course of illness was fairly typical,¹ except in the absence of fever, until the final stages of disease. Thrombocytopenia was particularly severe. Hypergammaglobulinaemia was present, and is typically found in these cases of chronic Q fever. Serological tests provide the best method of diagnosing these cases during life, and should be performed when, as in our case, blood cultures are negative. As in the present case, rickettsiae may also be isolated from unfixed vegetations, but this is a hazardous procedure which should not be attempted without safe laboratory and animal-house facilities.

The usual source of Q fever in this country is domestic animals or their excreta or birth-products, inhalation being the common route of infection. In the present case a gardener had been using untreated farmyard manure as a fertilizer a short time before the onset

of symptoms. Because of the gravity of Q fever endocarditis, which may not reliably be eradicated by the available rickettsiostatic drugs, it would seem advisable for patients with known or suspected damage to heart valves, or who have undergone cardiac surgery, to avoid contact with fertilizers based on farmyard dung as well as more obvious contact with sheep and cattle.

Rickettsial antigens were kindly provided by Professor M. G. P. Stoker (Phase 1) and by Dr. C. M. P. Bradstreet (Phase 2).

We are grateful to Dr. A. W. B. Edmunds for permission to report this case.

Restrictions on Doctor in South Africa

SIR,—A copy of your leading article (26 August, p. 512) and the letter from Lord Adrian and others (p. 556) were sent to me by airmail, and I greatly appreciated the terms of both the leading article and the letter. I regard both as fair comment. It may therefore seem strange that I have not written to you.

In the first place I did not feel free to do so because I was awaiting the outcome of an interview between the Minister of Justice and a deputation consisting of the Chancellor, the Chairman of the Council, the Principal and Vice-Chancellor, and myself as head of the University department in which Dr. Hoffenberg is employed. This deputation had correspondence with the Minister, who requested several memoranda which took time to prepare. As a result the interview has only just taken place, as has been reported in the South African press.¹ I therefore now feel free to comment.

However, now that I can comment I find myself reluctant to wash South African linen outside the Republic, I propose, therefore, to limit my own comment to the public press of South Africa.²

I have chosen the public press because I believe this to be a matter of common justice. The extent to which it involves international principles such as academic, scientific, and professional freedom is very deep and important, but primarily it is a civic matter which reflects many centuries of the history of democracy.—I am, etc.,

J. F. BROCK.

Case or Person?

SIR,—Emboldened by views expressed by Lord Adrian,¹ Sir Francis Fraser,² and recently by Lord Platt,³ I wish to comment on a case report from the Royal Postgraduate Medical School (28 October, p. 222) of a "case" of Crohn's disease in a patient with coeliac disease. Herein case No. 204058 is presented as an Irish housewife aged 34 at the time of her death. This non-person was

investigated with the thoroughness and brilliance that one expects and admires from this group of workers.

The absence of any personality profile of this patient, who spent some months in hospital, is, however, to be deplored not only on general grounds but for more specific reasons. Firstly, knowledge of her personality make-up would in my experience have exposed the personality characteristics so often described in psychosomatic disorders,⁴ and this would have produced a bias towards the correct diagnosis of Crohn's disease as opposed to the suspected intestinal lymphoma. Laparotomy might not then have been indicated. Secondly, it is conceivable that this patient had only one disease—Crohn's—for, on the one hand, there was no evidence pointing to the date of its onset, and, on the other hand, we already know that severe villous atrophy has been previously observed in Crohn's disease.⁵ Further, it is known that in dermatitis herpetiformis⁶ and in rosacea⁷ varying degrees of jejunal mucosal atrophy have been found in three-quarters of a series of the former and in one-third of a series in the latter. This association of skin and intestinal mucosal disorder would hardly surprise an embryologist. The discovery of these intestinal changes certainly enlarges the concept of these skin diseases, but no one would suggest that these patients had two diseases. Partial villous atrophy has been described in ulcerative colitis⁸ and in an increasing variety of conditions. The normal dynamics of mucosal replacement in the upper intestine presents an astonishing phenomenon, and a survey of its abnormalities in a greater number of conditions—including psychological stress and psychosis—could lead to a recognition of some of the determinants of these mucosal changes.

I certainly do not decry the importance of chemical and other organic studies at every level in diseases in which psychosomatic factors are present (Dr. G. L. Engel, 7 October, p. 56). Nevertheless, man is not the sum of his chemical processes. Case No. 204058 was a woman, and one must regret that her social and psychological history was not described.—I am, etc.,

London N.W.8. HUGH GAINSBOROUGH.

Thyroid Hormone and Catecholamines

SIR,—Dr. E. Grunwaldt (14 October, p. 109) rightly points out that experimental evidence in man and animals is available which suggests that thyroid hormone does not augment the actions of catecholamines on the cardiovascular system. He does not point out, however, that there is a considerable body of opinion that is in favour of such a relationship between thyroid and autonomic activity, and which believes that the failure to demonstrate it in experimental situations is due to lack of a suitable model system.

Exaggerated responses to catecholamines in thyrotoxic patients have been demonstrated.¹ Peripheral manifestations of hyperthyroidism in the cardiovascular system and in the eyes (lid lag and lid retraction) have been shown to be reduced or abolished by sympathectomy and by sympathetic blocking drugs.^{2,3} The efficiency of a pure beta-adrenergic receptor blocking drug in reducing thyrotoxic tremor⁴ and tachycardia⁵ has also been demonstrated. There is no convincing evidence that thyroid hormone increases plasma or tissue levels of catecholamines, but Brodie *et al.*⁶ have shown that it produces a rise in tissue adenylyl cyclase activity. It is tempting to suggest that this would lead to increased stimulation of cyclic 3',5' adenosine monophosphate by catecholamines, and this would explain increased responsiveness to normal levels of catecholamines in hyperthyroidism. The possible relationships between catecholamines and cyclic 3',5' adenosine monophosphate especially on heart muscle has been extensively reviewed.⁷

This increased sensitivity in thyrotoxic patients to catecholamines might explain why certain beta-adrenergic receptor blocking drugs that possess intrinsic sympathomimetic activity may fail to reduce thyrotoxic tachycardia, whereas similar drugs that do not have this particular activity can be employed successfully in the same patient.⁸—We are, etc.,

Complication of Thyroid Cancer

SIR,—We were very interested to read the review by Dr. K. E. Halnan and Mr. P. H. Roberts of nine patients with paraplegia caused by spinal metastases from thyroid carcinoma (26 August, p. 534), and, as their search of the literature revealed very few cases, we thought it would be of interest to record another case.

A 13-year-old African male was admitted to hospital with a history that he had been in good health until three weeks prior to admission. He then developed pain in the lower lumbar region radiating into both knees. Accompanying this he noticed he was having increasing difficulty with walking and his gait was unsteady. He had no bladder or bowel symptoms. Examination showed a well-built boy with a keloid neck scar. No abnormality was noted in the systemic examination of any system except in the C.N.S., where there was a paraplegia in extension with weakness, increased tone, and bilateral extensor responses, but no wasting, fasciculation, or sensory loss was detectable. Investigation showed a normal blood picture, alkaline phosphatase 31 King-Armstrong units, E.S.R. 30 mm./hour, and normal chest x-ray. Lumbar

puncture showed clear fluid under normal pressure, with increased protein of 120 mg./100 ml., normal sugar, and a white cell count of less than 1/cu. mm. An x-ray of the lumbar spine was normal. A myelogram showed a complete block at the level of T8. The neck scar was the result of a thyroidectomy performed in December 1962, and the histology report at that time was reported as being possibly malignant.

This boy was operated on by Mr. L. F. Levy, and a laminectomy was performed at the level of T7, T8, and T9. An oval tumour measuring 1½ in. by 1 in. (3.5 cm. by 2.5 cm.), apparently extradural in site, was easily lifted from the dura with extensive bleeding. Postoperatively he made an uneventful recovery and is walking quite satisfactorily. Microscopy of this tumour suggested metastatic carcinoma from the thyroid gland.

Dr. Malcolm Ross reviewed the old sections and reported on the present one, and gave his opinion that both showed thyroid carcinoma.—We are, etc.,

Warming Blood

SIR,—The letter from Dr. B. Philpott and Dr. I. P. Slee (14 October, p. 111) refers to Grant Laboratories' standard J.B.1 water bath. Several of your readers have had some difficulty in tracing us under this title, so I should like to confirm that we are the makers of the bath.—I am, etc.,

C. H. CHAPMAN,
Managing Director,
Grant Instruments (Cambridge) Ltd.
Cambridge.

SIR,—Dr. B. Philpott and Dr. I. P. Slee point out in their letter (14 October, p. 111), quite rightly, that there are other methods of warming blood besides that described by Mr. F. Alladine and myself (23 September, p. 787), and describe the use of a laboratory water bath.

Although primarily we were interested in producing a compact instrument which was convenient in use and unobtrusive in the theatre, there were essential considerations of safety, some of which should be mentioned. A second safety thermostat was thought to be essential to avoid overheating in the event of failure of the control thermostat, and this is lacking in the unadapted laboratory instrument. Moreover, the latter instrument, in a size convenient for theatre use, relies upon convection currents to mix the water, with the coil of blood overlying and very near the heating element. We decided that this was at least potentially hazardous, and so isolated the heating element and made use of a water impeller to reduce temperature gradients. Lastly, there was added a built-in thermometer, and the compartment to contain the coil was made of transparent material to permit continual observation of the blood in the coil. Of course, these considerations have added to the cost, but they have also added an essential element of safety.

We were aware of the potential hazards of vinyl plastic drip extensions, which are not normally warmed. Pharmax Ltd., who now market the Seeco Haemoguard, as the machine is now called, are also producing

the ready-made coils, and have been very helpful in providing the appropriate information on the British standard for testing this material—that is, B.S.2463, 1962. Animal tests for toxicity are carried out on the extracts of tubing heated to 85° C.—well above the temperature used in warming blood. So far we have no evidence of harmful effects on the blood, or on patients receiving warmed blood, though the results of further testing will be published in due course.—We are, etc.,

Fallacies in Four Fevers

SIR,—In your issue of 28 October (p. 237) Drs. J. P. Telling and J. M. Morfitt draw attention to the fact that the latest edition of the joint memorandum of advice to school medical officers was in 1956 and that the periods of exclusion given are now thought by some to be excessive. If an authority is required to support advice for shorter periods this may be found in that invaluable but too little known handbook *Control of Communicable Diseases in Man*.¹ An introductory note states that "The substance of this report has been accepted by the Ministry of Health for England and Wales, the Scottish Home and Health Department. . . ." The advice given for the four fevers is as follows.

Measles. Isolation: From diagnosis until 7 days after appearance of rash. . . . Schools should not be closed nor classes discontinued.

Rubella. Isolation: None, except where contacts include a woman in early pregnancy; then under direction of the attending physician for 5 days after onset.

Mumps. Isolation: For 9 days from onset of swelling; less if swelling has subsided.

Chicken-pox. Isolation: None; exclusion from school for one week after eruption first appears and avoid contact with susceptibles.

This advice cannot be regarded as unduly oppressive.—I am, etc.,

J. C. KELSEY.

Central Public Health Laboratory,
London N.W.9.

Teaching the Behavioural Sciences

SIR,—Everyone, I am sure, will welcome the timely leading article entitled "Teaching the Behavioural Sciences" (21 October, p. 123), and will support the suggestion that this teaching should run as a thread throughout the preclinical and clinical courses. Much of the teaching will be focused upon the daily lives and activities of both the sick and the healthy where clinicians from various specialties are already engaged in the study and management of the behavioural aspects of health and disease. This is in fact the essence of paediatric practice.

The omission of child health from the list of clinical subjects concerned with the behavioural sciences was presumably unintentional; there have been many paediatric contributions to this topic. Examples readily come to mind: teaching about normal and abnormal development,¹ stimulating the prac-

tice of developmental paediatrics,² encouraging the visiting of children in hospital,³ and awakening concern for the welfare of the under fives.⁴

It is to be hoped that curriculum committees will not forget the contributions which child health has made, and will continue to make, to the study of the behavioural aspects of health and disease in childhood and the subsequent application of these lessons in practice.—I am, etc.,

KENNETH HOLT.

M.A.O. Inhibitors and Headache

SIR,—Perhaps I can throw some light on Dr. C. A. H. Watts's observation of monoamine oxidase inhibitor headache without hypertension (28 October, p. 238).

Severe headache, the result of acute but often short-lasting hypertension following monoamine oxidase inhibitor antidepressant drugs, is well documented.^{1,2} There is much evidence in these cases to suggest that the elevation of blood pressure and consequent headache are due to cumulative inhibition of intestinal amine oxidase, with a resultant "enhanced" pressor action of various biologically active amines (dopamine, and particularly tyramine), which occur naturally in certain foodstuffs³ (cheese, Marmite, broad beans, chicken livers, etc.). Although I believe that hypertension probably accounts for the majority of severe headaches following monoamine oxidase inhibitor drugs and cheese, it is clear that other mechanisms may be involved, since severe headache has occurred without such changes in the blood pressure.^{4,5}

During the natural maturation of cheeses, although conditions favour the formation of tyramine,⁶ histamine is occasionally formed⁷; histamine is present more constantly and in much greater concentrations in Marmite.⁸

Monoamine oxidase inhibitors are known to interfere with histaminase,⁹ an enzyme which inactivates histamine; for this reason the physiological actions of exogenous histamine derived from foodstuffs or endogenous histamine or both, the release of which is promoted by organic bases present in many foods, may be greatly augmented and produce clinically observable effects. The histamine hypothesis is supported by Mathov's¹⁰ observation that over 50% of a series of asthmatics he studied showed clinical deterioration following treatment with a variety of monoamine oxidase inhibitors.

Histamine may induce a variety of toxic manifestations in humans, including severe occipital headache, hypotension, anginal pain, blurred vision, colic, diarrhoea, urticaria, "asthmatic breathing," and excessive secretion of salivary, gastric, and lacrimal glands, etc. It is easy to see how one or several of these "toxic symptoms" could occur following monoamine oxidase inhibitors and cheese.

In the individual case the particular toxic symptoms following monoamine oxidase inhibitors and cheese, Marmite, or other foods probably represents the algebraic summation of the respective and often antagonistic physiological actions of tyramine or histamine and perhaps other biologically active amines (the concentrations of these naturally occurring amines in any foodstuff depends upon manufacturing processes, and has been shown to be subject to considerable variation), as well as the degree of gut amine oxidase inhibition, which if complete may allow comparatively large quantities of tyramine or histamine or both to be absorbed into the bloodstream and produce spectacular toxic effects.

In Dr. Watts's patients who experienced headache without hypertension histamine rather than tyramine seems the likely cause. The simultaneous clinical occurrence of other histamine-like effects, as enumerated above, would support such a contention. In these cases the logical antidote would be antihistamines.—I am, etc.,

Railroading in Retinal Vessels

SIR,—There has been considerable correspondence lately regarding the appearance of the retina at death. Mr. A. C. Gillies (28 October, p. 236) writes about the late Dr. Gulland, of Edinburgh, who made "discoveries," including railroading in the retinal vessels, around 1922.

To Mr. Gillies, and to others interested, I must state that Dr. C. Usher, who did so much original work in the eye department at Aberdeen, gave a full description of the fundus appearances in *Ophthalmic Review*, 1896.¹—I am, etc.,

CHARLES COCKBURN.

Multiple Sclerosis in South Africa

SIR,—Dr. J. F. Kurtzke in his letter (16 September, p. 739) about my paper on multiple sclerosis in South Africa (17 June, p. 724) commented that it would be most helpful if I could provide a further table for the 72 European immigrants from Europe to South Africa who had their first symptoms of multiple sclerosis in South Africa, listing the ages at immigration, at onset of symptoms, and at prevalence day. He suggested that such a table might provide further information on the hypothetical "incuba-

tion" or latent period between presumed disease onset and symptom onset.

These are the details that Dr. Kurtzke requests:

Age at Immigration, Onset of Symptoms and at Prevalence Day of 72 European Immigrants (Multiple Sclerosis)

Age at Immigration	Age at Onset	Age at Prevalence Day	Age at Immigration	Age at Onset	Age at Prevalence Day
2	35	35	26	36	40
3	21	25	26	32	47
3	29	40	26	35	56
5	23	35	27	29	31
7	41	53	27	37	67
7	30	62	27	29	59
9	39	48	28	45	51
10	18	42	28	43	49
10	18	61	28	39	41
15	40	54	28	36	61
16	33	52	28	43	66
16	37	40	29	30	47
16	23	42	29	40	54
17	25	38	29	32	39
17	29	51	30	41	44
17	29	38	30	43	56
17	30	51	31	38	41
17	34	43	31	42	43
18	38	58	32	43	44
18	23	37	33	41	67
18	35	61	33	35	46
18	24	65	33	40	52
19	35	68	34	38	46
19	42	59	35	47	49
20	29	40	37	39	50
21	23	69	39	40	53
21	31	59	39	41	48
21	24	31	39	54	69
22	29	30	40	42	51
22	35	40	41	44	47
22	28	53	41	52	64
23	24	25	42	47	53
24	34	43	43	47	55
24	44	58	47	49	58
25	46	52	52	53	56
25	38	47	53	54	62

I hesitate to make any comments as to how the table should be interpreted.

Dr. Kurtzke is impressed, as I was myself, by the high proportion of English-speaking South African born multiple sclerosis patients who had visited Europe (46 out of 101), 39 of these before the onset of multiple sclerosis. Nevertheless, when the English-speaking South African born controls are matched by sex, age group, and by birthplace of parents the "expected" number to have visited Europe (40.5) is not significantly different from the actual number (46). The controls must be matched by birthplace of parents because a higher proportion of the English-speaking South African born multiple sclerosis patients (40 out of 101) than of the English-speaking South African born population at risk matched for age and sex only (23.5), had both parents who had been born in Europe.

It is not therefore correct for Dr. Kurtzke to take only the remaining 55 out of 101 English-speaking South African born and divide 55 by the total English-speaking population at risk, bringing the rate down from 11 per 100,000 (101 out of 925,000) to 6 per 100,000 (55 out of 925,000) as compared with the rate for the Afrikaans speaking of 3 per 100,000.

Dr. Kurtzke suggests that multiple sclerosis is perhaps caught in the high risk area and brought to the low risk area rather than vice versa. This, I agree, is a possible explanation—however, the low risk areas are those that particularly favour infection early in life. Furthermore the higher risk in the English-speaking than in the Afrikaans-speaking white South African born and the higher risk in the upper economic class that Kurtzke has shown occurs in the United

States¹ and which has also been reported in the United Kingdom^{2,3} suggests that multiple sclerosis is, like poliomyelitis, an infection which if caught early in infancy is not likely to cause neurological damage. If, on the other hand, the infection is delayed the pre-disposed may develop the syndrome we know as multiple sclerosis.—I am, etc.,

Port Elizabeth,
South Africa.

Mushroom-worker's Lung

SIR,—I read the article on mushroom-worker's lung by Dr. A. Sakula (16 September, p. 708) with much interest, for mushroom production is a local industry. In particular, I was struck by the similarity of Case 3 to a patient I saw in 1965, and I am prompted to give details.

He was aged 55, and he had worked on a mushroom farm for three years in connexion with the spawning process. Late in April 1965 he developed troublesome breathlessness, together with non-productive cough, anorexia, tiredness, and weakness, and he had to stop work. A chest x-ray showed extensive fairly coarse reticulonodular shadowing throughout both lungs, with some coalescence but no hilar lymphadenopathy. The nature of his work raised the suspicion that these appearances were due to extrinsic allergic alveolitis, but precipitin tests with his serum were negative. A Mantoux test (1:100) was also negative. Biopsy of a scalene node, however, showed changes considered to require recognition as sarcoidosis.

The diagnosis in this patient was proved only by biopsy. Undoubtedly a few individuals with occupational lung disease do have negative precipitin tests, but in the present state of knowledge when this is so I suggest that sarcoidosis does need to be excluded, histologically if possible, either by examination of a scalene node or a Kveim test. As Dr. Sakula recognizes, both types of illness are not dissimilar, and one knows that in some instances they can be differentiated only by biopsy methods. I feel it would have been interesting to have studied tissue from his Case 3. Admittedly this patient was tuberculin positive, but, although tuberculin sensitivity is frequently depressed or absent in sarcoidosis, it is not invariably so.

Dr. J. Edgar Morison, of the department of histopathology, Belfast City Hospital, recently re-examined the scalene gland obtained from my patient (personal communication). He confirmed that it showed granulomatous lesions indistinguishable from Boeck's sarcoidosis. He points out that, in contrast with sarcoidosis, and as far as is known at present, granulomatous lesions in farmer's lung do not extend beyond the lung. Presumably this also applies to other forms of allergic alveolitis of similar aetiology. The occurrence of acute sarcoidosis in this mushroom worker probably was fortuitous and coincidental, but it is impossible not to speculate that it might have resulted from exposure to something at work, as in beryl-

liosis. However, there is no indication of what this could have been, and there have been no other comparable cases.

Finally, in Dr. Sakula's Cases 1 and 2 an association between their work with mushrooms and the respiratory symptoms certainly appears likely, although the precipitins in their blood might possibly have resulted from dust exposure during previous jobs. The indications are that serum precipitins, once induced, can persist for eight years at least.—I am, etc.,

Northern Ireland.

Stress Incontinence

SIR,—I have been interested to read the recent articles on the treatment of stress incontinence by electrical stimulation of the levator muscles by Mr. T. Moore (16 September, p. 740) and Mr. S. A. Vincent (19 August, p. 498).

Mr. K. P. S. Caldwell (21 October, p. 175) states that he has observed a "lift forward" of the bladder neck on stimulation and that "this fits in well with the theories of continence put forward by Jeffcoate and the Liverpool school."

I should like to draw these authors' attention to my own articles.¹⁻³ In these the development of the operation of colpo-fixation for the worst cases of stress incontinence in the female was based upon the physiological theories enunciated in Liverpool. This operation, which elevates and fixes the upper urethra to effect a permanent cure, was followed up in more than a hundred cases over periods of two, five, and ten years to show a symptomatic and anatomical cure rate of over 80% after 10 years.

The treatment of this condition by electrical stimulation of the admittedly weak and attenuated levator and perineal muscles must therefore stand the test of time such as this in order to show itself of more than temporary benefit and thus to prove its worth.—I am, etc.,

Manchester.

Glycosuria in Pregnancy

SIR,—I would appreciate an opportunity of replying to Dr. T. Lind (24 June, p. 841).

Dr. Lind states that the glucose oxidase method of estimating glucose in urine is valueless for small quantities up to 5 mg./100 ml.

He will change his mind if he cares to dip a Clinistix paper into a 5 mg./100 ml. glucose solution and obtains a distinctly blue colour; he will also get a recognizable change with 2.5 mg./100 ml. The oxidase test is more sensitive than Clinistix, since the reaction continues to completion, and detection of colour change is enhanced by the use of a spectrophotometer with appropriate colour filter. He also criticizes the method because of the loss of glucose which occurs when urine is treated with charcoal. I observed this loss early in my study of the method, and solved the problem it involved by the two-tube

method described in my first paper (8 May, 1965, p. 1209). The first tube contained urine alone, the second had 10 mg./100 ml. glucose added. The difference in the extinction readings represented 10 mg./100 ml. glucose, whatever the glucose loss, which in any case rarely exceeds 20%.

This loss, incidentally, is partly due to charcoal adsorption and partly to residual antienzyme action. I agree that occasionally charcoal fails to remove the antienzymes, rendering it impossible to analyse the glucose in the urine. Such cases are excessively rare, and only a few specimens were discarded for this reason out of thousands examined. As for persistence of yellow colour in the filtrate, this can occur if a poor quality of activated charcoal is used, but in any case it does not invalidate the method provided the urine antienzymes are substantially reduced. The optical density of the yellow filtrate can be read and an appropriate deduction made from the final extinction readings. Variation in results due to time and temperature, and differences in results when identical samples are analysed, are in my opinion due to lack of experience in the technique. I have trained large numbers of technicians who all eventually emerged from the early stage of crudity of performance.

I think the best evidence of the remarkable ability of the glucose oxidase method to detect slight variations in urine glucose level is revealed in the glucose tolerance test studies described in Table VI of my first paper. In each of the eight cases a rise of a few mg. is demonstrated in the normal volunteers following ingestion of 50 g. glucose, and the suggestion that this is due to experimental error is less than tenable.

Dr. Lind thinks that the hypoglycemia and hyperglycemia of pregnancy are figments of my imagination born out of experimental error. I would therefore invite him to examine the chart (Fig. 4 in my second paper) illustrating the shift in the histogram values from pre- to post-delivery populations. Does he seriously consider that the raised incidence of hypo- and hyperglycemia in the pre-delivery group is due to technical errors which mysteriously evaporate after delivery?—I am, etc.,

Pathological Laboratory,
Kitwe Central Hospital,
Kitwe, Zambia.

J. FINE.

Aspirin and Gastric Bleeding

SIR,—It is surprising that in your recent leading article on aspirin and gastric bleeding (30 September, p. 810) there was no consideration of the role of gastric acidity in the pathogenesis of this troublesome side-effect.

It has been known for many years that the irritant effect of sodium salicylate can be reduced by the simultaneous administration of sodium bicarbonate, and more recently there have been a number of observations suggesting that the irritant effect of aspirin might be, similarly affected by changes in gastric acidity. Thus the incidence of bleeding from the stomach is reduced when aspirin is given with an excess of sodium bicarbonate,¹ and it has been found that patients with atrophic gastritis or achlorhydria are less susceptible to aspirin-induced bleeding (23 January, p. 137).

Aspirin is a relatively strong acid, and in the unbuffered gastric juice will be largely in the form of the undissociated molecule. At the pH of the plasma and in the intra-

cellular fluid the concentration of the molecule will be very small indeed, and the drug will be almost entirely in its anionic form. The pharmacological effects of the salicylates are related to the intracellular concentration of their anions, and by "non-ionic diffusion"; this is related to the pH gradient across the cell membrane. There is no reason to suppose that the gastric mucosal cells are different from other cells with respect to their intracellular pH, and so the pH gradient across the luminal membrane may be very high indeed. Even at moderate levels of gastric acidity, say pH 5, the concentration of the acetylsalicylate anion within the mucosal cell may be as much as 100 times the concentration of the anion in the gastric juice. With this in mind it is scarcely surprising that haemorrhage from the gastric mucosa may follow the ingestion of aspirin, even when this is given in the soluble form after meals.¹

If this interpretation is correct aspirin-induced gastric bleeding should be preventable by maintaining the gastric pH at or even higher than pH 7 while the drug is being absorbed. Merely to buffer the acetylsalicylate itself is not sufficient; the hydrochloric acid produced by the stomach must be neutralized as well to an extent beyond that normally achieved in the treatment of duodenal ulcer. The use of sodium bicarbonate for this purpose will render the urine alkaline and increase the excretion of salicylate. However, it may well protect the cells of the distal tubule and collecting duct from a similar pH gradient and destructively high intracellular concentration of salicylate anion as is found in the gastric mucosa.—I am, etc.,

Royal Infirmary,
Edinburgh.

Conservative Treatment of Fractured Femur

SIR,—It is the practice in many centres to treat grossly comminuted fractures of the femur either in a Thomas splint or in some sort of sliding traction. This leads to many difficulties in nursing, pressure sores, bowel and urinary trouble, venous thrombosis, and hypostatic pneumonia. In addition, frequent adjustment of the splint, weights, etc., is necessary, and if the patient survives the leg may still be malunited and short. This is a genuine problem, especially in hospitals where such cases are perforce treated in busy general surgical wards.

For the past two years I have treated such cases, when over 70 years of age, as follows. Shortly after admission, once conservative treatment has been decided upon, a well-padded cast is applied from toes to mid-thigh. An antirotation bar (wood) is incorporated on the sole and just above the knee. Two plaster loops are also made just below the knee, so that traction can be easily applied. The limb is held, correctly rotated, and shortening of 1 in. (2.5 cm.) is accepted, and indeed attempted, thus allowing "controlled collapse."¹ The fracture is generally quite sticky in four weeks, when the plaster is converted to a below-knee one. Active

movement is insisted upon from the start. In six weeks the plaster is removed, and by the tenth week the patient is at home with partial-weightbearing crutches. The results achieved are gratifying, and both patient and nurses are spared time and trouble.—I am, etc.,

Vasectomy for Contraception

SIR,—In his letter (11 November, p. 354) Mr. Donald Young refers to the opinion of counsel which the Medical Defence Union obtained in 1949 regarding the legality of sterilization. The Union's legal advisers are no longer of the opinion that an operation for sterilization is unlawful, whether it is performed on therapeutic or eugenic grounds or for any other reason, provided there is full and valid consent to the operation by the patient concerned. It must be emphasized, however, that this opinion is not based on a statute or judicial authority, because the proposition has never been tested in the courts. Nevertheless, our legal advisers are confident that a surgeon who complies with a patient's request that he be sterilized would not be committing an offence.

Attention was drawn to this change in view in my letter published in your columns (25 June 1966, p. 1597) and on p. 14 of the Union's 1966 Annual Report.—I am, etc.,

PHILIP H. ADDISON,
Secretary, Medical Defence Union.

London W.C.1.

Fluoridation of Water Supplies

SIR,—Dr. R. L. Kerr (21 October, p. 176) takes the Minister of Health to task for doing his duty in trying to improve children's teeth and save them from unnecessary pain. Then followed the usual anti-fluoridation letters. The facts are that there are over 50 million people drinking fluoridated water (1 p.p.m.) in North America and about two million in Britain. Fluoridation is the official policy of the Ministry of Health, the Public Health Authority in the U.S.A., the World Health Organization, and, so far as I know, every reputable health authority in the civilized world. It also has the blessing of the law. In the Lower Hutt case, which was brought before the Judicial Committee of the Privy Council, Lord Upjohn, giving the judgement of the Board, said:

"The water of Lower Hutt was no doubt pure in its natural state, but it was very deficient in one of the natural constituents normally to be found in water in most parts of the world. The addition of fluoride added no impurity and the water remained not only water but pure water and it became a greatly improved and still natural water, containing no foreign elements."

"No Change"

SIR,—In the recent ballot 1,783 votes have been cast in favour of stopping all merit awards, 1,670 voters are in favour of continuing the present system, 4,639 voters desire a change away from the present method of distributing these awards, and 5,272 voters support the continuation of some system of merit awards. The writer of your leading article on this subject (21 October, p. 128) interprets these figures as a mandate for "no change."

These figures indicate that there should be rewards for special merit within the hospital service, and that the present system is not acceptable. The Council of the Association has in fact been given a clear mandate to initiate reform of the merit awards system. The comments of the *B.M.J.* leader writer on this subject appear to me to conflict with the voting figures. Any Council member who has been tempted to accept a like conclusion should consider the effect that failure to tackle this problem resolutely may have on the substantial majority of the voters in this ballot who consider a change is necessary.—I am, etc.,

JOHN K. MCCOLLUM.

Newcastle upon Tyne.

SIR,—I have read your leading article (21 October, p. 128) "No Change" with great interest: I agree with you that it is a pity that there was only a 50% poll, but this is generally attributable to the confusion caused by the ineptness of the question pattern and to the fact that the poll was held at the height of the summer holiday season. There is no doubt that a public announcement by the Council to the effect that these defects arose by accident rather than design is called for and might do something to restore confidence in the Central Consultants and Specialists Committee.

With regard to the leading article it would appear that, concerning question five, 5,272 replies could be in favour of some revised system of merit awards, but in addition to this number a further 4,639 state definitely that the present system requires change. There can be no doubt whatsoever as to the statistical significance of the similarity between these two sets of figures.

From the figures quoted on the results of the ballot on the questions asked, there is no justification whatsoever for saying there is a mandate for "no change." To say that there is to be deliberately misleading, and I am most surprised that you should lend yourself to this sort of thing.—I am, etc.,

Winchester.

C. REMINGTON-HOBBS.

* The change most widely called for was for less or no secrecy. Only 1,532 of those who replied made this comment—about one-fifth—or about 10% of those to whom the questionnaire was sent.—ED., *B.M.J.*

Night Visits

SIR,—I was most interested to read of Dr. J. D. Wigdahl's failure to submit forms in respect of night visits to patients who

were very ill or subsequently died (23 September, p. 802). This of course will be common practice on the part of general practitioners who feel that to submit their one and only "bill"—especially for such a paltry sum—at perhaps the most worrying and harrowing time in a patient's life is somehow morally wrong, out of place, badly timed, and rather debasing to one's Hippocratic oath. Of course the Ministry of Health realizes this and it knows that such a form sent for signature to the patient is tantamount to telling the patient that his general practitioner is a bit of a rogue, completely untrustworthy, and not just the sort of fellow anyhow to be treating a near and dear relative, perhaps their only child, at such an important and dreadful crisis in life—and after all wasn't the Ministry right, because perhaps the patient died?

Similarly, in our area we have been having the most infuriating trouble over having "emergency treatment" paid for. Each form is scrutinized in minute detail, many letters are written to general practitioners asking why they didn't treat their patient four miles away, when they didn't even know their patient had lacerated his hand at work, or fallen over the cliff. This again has resulted in some practitioners stating that they are not going to submit another "emergency treatment" form; another victory for the Ministry.

The answer is a vastly different type of Health Service, where payment is by item of service, which will almost double the general practitioner's income; where there will be incentives to acquire new knowledge and skills, because he will be paid extra for using them; where he will be relatively free from the stupid petty frustrations of today; where he will have time to do his work, because those who are able to do so will have to pay to see him, and pay for part of the cost of their drugs (about 70% of the population); and where he will regain the respect of his hospital colleagues, because he will have time to do worthwhile work in view of the fact that much of the other kind of work will disappear.

Does all this seem like Utopia? Well, you can take it from me that it is; unless in desperation we have the courage to fight for what is worth while.—I am, etc.,

Peterhead,
Scotland.

G. I. LUMSDEN.

Service Overseas

SIR,—May I be permitted to comment on views expressed at the first meeting of the Committee on Overseas Affairs (*Supplement*, 21 October, p. 20)?

It will be recalled that many of these views, in so far as they relate to the emergent countries of Africa, formerly British Colonies or Protectorates, were admirably stated in your leading article under the title "Africa's Need."¹ These were commented upon subsequently.^{2,3} As regards service overseas after retirement, this proposal was raised in a private report⁴ passed to officials of the Department of Technical Co-operation in July 1964. For several reasons, some quite obvious, a period of two years abroad for a doctor aged 65 might be too exacting, though clearly the Medical Adviser to the Ministry of Overseas Development was wholly justified in remark-

ing that "three months would neither be useful nor economically feasible." This aspect of overseas aid offers some scope for further discussion, but the overall response among retired general practitioners or consultants from the United Kingdom is unlikely to be significant.

Consideration also by the Committee of a letter from the Ministry of Overseas Development raised points that might have far-reaching importance. They could ultimately permit a much more realistic approach to the urgent needs of clinical departments overseas and relate them far more closely to requirements in Britain within the National Health Service. Furthermore, it is well known that there have been instances, perhaps isolated, where doctors returning from overseas have been resettled at a disadvantage. Officials of the Ministry of Overseas Development know quite well it would always be very difficult to prevent disadvantageous resettlement inasmuch as advisory appointments committees at regional board level in this country could never be influenced directly in favour of a returning expatriate.

It seems therefore abundantly clear that doctors in all grades should in future go overseas only on secondment, and it is hoped the Committee will henceforward urge the establishment of central sources of supply of manpower for overseas to be administered at each regional level by a small standing overseas committee.—I am, etc.,

Liverpool 1.

Signs for Doctors' Cars

SIR,—I note that the Private Practice Committee (*Supplement*, 7 October, p. 9) intends to issue 2,000 self-adhesive signs for doctors' cars.

Having had a supply of these since the Annual Representative Meeting, I would urge that this plan be scrapped, as they are quite useless. Owing to the transparent background and small size the words are almost invisible beyond the car's bonnet. Please think again, Private Practice Committee, as a matter of urgency.—I am, etc.,

Edgware,
Middlesex.

A. D. MANNING.

Points from Letters**Menace of Smoking**

Dr. E. B. GROGONO (Woodford Green, Essex) writes: I read your leading article (23 September, p. 753) and hoped that so important a topic might provoke a lively correspondence. Twenty thousand avoidable deaths in Britain per year are surely more important than many of the rare topics we discuss in the *B.M.J.* I believe that, as a profession, we have set a moderately good example, and I have the impression that cigarette-smoking is far less common among students, medical students in particular, than it was 20 years ago.

Obituary Notices

M. DAVIDSON, M.A., D.M., F.R.C.P.

Dr. M. Davidson, a leading authority on diseases of the chest, and consulting physician to Brompton Hospital and the Miller General Hospital, London, died in hospital on 8 November. He was 84.

Maurice Davidson, son of the late Professor Alexander Davidson, emeritus professor of pathology in University College, Liverpool, was born in Liverpool on 30 August 1883. From Liverpool College he entered Trinity College, Oxford, where he graduated B.A. in 1905 with second-class honours in physiology in the final school of natural science.

He went to University College Hospital, London, for his clinical training, and graduated B.M., B.Ch. in 1908, taking the M.A. the same year. He held early appointments at University College Hospital, Huddersfield Royal Infirmary, and the Hospital for Sick Children, Great Ormond Street, before becoming medical registrar and tutor at St. George's Hospital. He proceeded D.M. in 1912 with a thesis on gastric secretion in anaemia and chlorosis, with reference to their relation to gastric ulcer. A year or so before the outbreak of the first world war he moved to Southsea, where he was honorary medical officer to the home for convalescent children. His service as a temporary captain in the R.A.M.C. during the war took him to Gallipoli, Sinai, Egypt, and Palestine.

After demobilization Davidson settled in London, taking the M.R.C.P. in 1919, and being elected F.R.C.P. in 1927. In 1920 he was appointed physician to the Miller General Hospital, where he became senior physician, and, ultimately, consulting physician. In the same year he was appointed physician to outpatients at the Royal Waterloo Hospital for Children. Appointed assistant physician at the Brompton Hospital in 1921, he became full physician a few years later and, subsequently, consulting physician. For five years he was dean of the medical school at the Brompton. He was also consulting physician to St. Luke's Hospital, Chelsea, St. Stephen's Hospital, and the Western Ophthalmic Hospital; honorary consulting physician to the Papworth Village Settlement and the Manor House Hospital; and associate physician to the Royal Marsden Hospital.

When the British Medical Association held its Annual Meeting at Oxford in 1936 he served as a vice-president of the section of tuberculosis. For a number of years he represented the section of medicine (of which he had been president) on the editorial committee of the Royal Society of Medicine, being for a time honorary editor of the *Proceedings*.

He was a senior member of the Thoracic Society.

In 1952-3 Davidson delivered the FitzPatrick Lectures before the Royal College of Physicians of London on "Medicine in Oxford, a Historical Romance." The lectures were subsequently published in book form. He was the author of *Cancer of the Lung and other Intrathoracic Tumours*, published in 1930; *A Practical Manual of Diseases of the Chest*, which appeared in 1935 and ran through several editions; and *The Diagnosis and Treatment of Intrathoracic New Growths*, printed in 1951. He also wrote in 1954, jointly with Mr. F. G. Fouvray, *The Brompton Hospital: The Story of a Great Adventure*, and in the following year he produced a handsome volume entitled *The Royal Society of Medicine: The Realization of an Ideal, 1805-1955*, a book written to commemorate the 150th anniversary of the founding of the Medical and Chirurgical Society of London, now the Royal Society of Medicine. *Memoirs of a Golden Age* appeared in 1958, and *Destiny and Freevill* in 1962. He was editor and contributor of *Medical Ethics: A Guide to Students and Practitioners* (1957). He also contributed articles on diseases of the lung to the second edition of the *British Encyclopaedia of Medical Practice*.

In 1913 Davidson married Gretchen Lucy, youngest daughter of the Rev. H. Bolton Smith, vicar of Wymering, Hampshire, and they had a daughter and three sons. His wife died in 1963.

F.H.Y. writes: If during the period after the war a ballot had been taken among the staff of the Brompton Hospital, both medical and lay, to decide who was the most-loved member, Maurice Davidson would undoubtedly have headed the poll. He was a good physician of the old school, careful and kind, slow to criticize and quick to praise. No one could have been quicker to condemn, and, if possible, remedy an injustice. His hospital patients adored him. His appearance was always neat, but he affected an old-fashioned type of dress, and his square bowler hat was familiar to us all. Before he was ill he was often seen walking along Harley Street wearing a speckled straw hat and a pair of sponge bag trousers. I remember well being telephoned by him in the 'fifties to ask if I could lend him a pair of white canvas spats, which he wished to wear at a wedding. He had searched London unsuccessfully to find a pair to replace those which were worn out. In some respects he was unlucky, as owing to the long period in which there were no vacancies on the staff he did not become a physician at St. George's; but this was to the advantage of the Brompton Hospital and the Royal Society of Medicine, as it gave him more time to devote himself to their welfare. He was devoted to Oxford, his Alma Mater, and this led him to choose Oxford as the subject of his FitzPatrick Lectures. The Royal Society of Medicine owed much to him, and in 1965

showed its appreciation by electing him an honorary Fellow. His home life was very happy, but saddened by the death in an accident of a much-loved daughter, and later by the loss of his wife. During the last few years he was dogged by ill-health, losing a leg by amputation, and subsequently had trouble with his eyesight; this latter was a sore trial to him as he was a voracious reader. But he took misfortune bravely, and was always cheerful. With his death we have lost an English gentleman in the best sense of the word.

F. BOYES KORKIS, M.B., CH.B.
F.R.C.S., F.R.C.S.ED.

Mr. F. Boyes Korkis, consultant surgeon to the Metropolitan Ear, Nose and Throat Hospital, Hillingdon Hospital, and Hayes and Uxbridge Cottage Hospitals, died as the result of an accident at sea on 7 November. He was 53.

Frederick Boyes Korkis was born in England at Rickmansworth, Hertfordshire, on 21 December 1913, but on the death of his father was taken at an early age to live in New Zealand, and hence became known to many of his friends and associates as a New Zealander.

He received his early education at King's College, Auckland, before entering Otago University medical school, where he graduated M.B., Ch.B. in 1937. The following year he came to England, where he trained under Lionel Colledge at the Throat, Nose and Ear Hospital, Golden Square, and obtained his Edinburgh Fellowship in 1941 and the D.L.O. in 1940. During this time he also met and worked with Scott Stevenson. He then returned to New Zealand, where he joined the 2nd New Zealand Expeditionary Force and served as otologist in Egypt, Palestine, and Italy, attaining the rank of major.

After demobilization Korkis was appointed registrar to the Metropolitan Ear, Nose and Throat Hospital before returning to New Zealand to start practice as assistant ear, nose, and throat surgeon at the Auckland General and Green Lane Hospitals. He soon established a busy and successful practice, and it seems likely that he would have remained in New Zealand had it not been for his earlier association with Scott Stevenson, who encouraged his return to England when a vacancy occurred on the staff of the Metropolitan Ear, Nose and Throat Hospital. He was appointed shortly before the National Health Service was inaugurated in 1948, and he continued to serve the hospital until his

(Elliott & Fry)

death, although its identity was lost within a regional organization when amalgamated with St. Mary Abbot's Hospital. Indeed, he was a most ardent and loyal supporter of the "Met. B.N.T.," and in his capacity as dean never ceased to work and plan for its future, even though many considered that officially its death certificate had been signed. He took the F.R.C.S. in 1949, and became consultant-ear, nose, and throat surgeon to a number of hospitals, including Whittington and Hillingdon, and was also appointed honorary otolaryngologist to the Royal Academy of Dramatic Art and the Royal Society of Musicians.

Fred Boyes Korkis was a man of exceptional ability with a wide range of interests, many of them outside surgery. As a surgeon he was quick, dexterous, and undaunted even by the most fearsome conditions, and his exceptional skill and remarkable *sang-froid* enabled him to impart great assurance and confidence to all within the operating-theatre. His surgical interests were wider than those often associated with his specialty, and embraced the "ear, nose, and throat" in its widest sense. The surgical treatment of malignant growths of the larynx and pharynx was a field in which he demonstrated remarkable skill. His performance of these intricate operations was admired and envied by the many visitors who came to watch him operate. But most of all he will be remembered for his kindness and consideration to all who sought his advice, and for the care and devotion so freely given to his patients.

The same exceptional talents were apparent in his other activities. Thus he showed the most remarkable ability to learn even the most complicated subjects with apparent ease. He never failed an examination for which he studied—his most recent achievement being in wireless telegraphy, in which he obtained the certificate of the City and Guilds radio amateurs examination. He taught himself photography and became an outstanding amateur photographer, using his talent to provide material to illustrate some of his books and articles. He was a prolific and lucid writer, publishing many papers on a wide variety of subjects, but he will be remembered more particularly for his book on *Bar, Nose and Throat Nursing*, published in 1955, and for his latest edition of *Recent Advances in Otolaryngology*, published in 1958, previously edited by Scott Stevenson.

Of recent years he became interested in sailing, and with characteristic enthusiasm set out to master the difficulties and to face the challenge of the sea. He became an enthusiastic member of the Rochester Cruising Club, and it is sad that this activity led to his tragic death.

He is survived by his widow and two young daughters, and an older daughter of a previous marriage, to all of whom we extend our sincerest sympathy.—G. E. H. E.

D. K. ADAMS, M.A., B.Sc., M.D.
F.R.C.P., F.R.C.P.GLASG.

Dr. D. K. Adams, honorary consulting physician to the Western Infirmary, Glasgow, died at his home on 6 November, aged 76.

Douglas Kinchin Adams was born on 29 August 1891. He was educated at Kelvin-side Academy and Glasgow University, and

after a brilliant academic career graduated M.A. in 1910, B.Sc. in 1912, and M.B., B.S. a year later. He became a house-surgeon at the Western Infirmary, Glasgow, with that great pioneer of surgery Sir William Macewen, whom he admired and frequently quoted. During the first world war he served in the Royal Navy, and on demobilization in 1919 he became an assistant to the late Professor T. K. Monro at Glasgow University, and also an extra dispensary physician at the Western Infirmary.

Outstanding among his colleagues in stature and intellect, he acquired a well-merited reputation as a clinical teacher. Keenly interested in diseases of the nervous system, he clarified many of the problems associated with that difficult branch of medicine for graduates and postgraduates alike. Disseminated sclerosis provided a life-long study and the subject for his M.D. thesis, which he was awarded with honours and a Bellahouston gold medal in 1921. He took the F.R.F.P.S.Glasg. in 1919 and the M.R.C.P. in 1926, and rapidly acquired an extensive consultant practice in the west of Scotland. He was elected F.R.C.P. in 1937 and became F.R.C.P.Glasg. in 1964. He was appointed visiting physician at the Ministry of Pensions hospital at Bellahouston, physician in charge of wards at Stobhill General Hospital, and later visiting physician in charge of wards at the Western Infirmary, Glasgow, which post he held until he retired from hospital work at the age of 65, when he was appointed an honorary consulting physician to the Western Infirmary.

"D.K." wrote little, but his few articles were of a high order and always commanded attention. His impact upon the Glasgow School of Medicine came mainly from clear and brilliant clinical teaching, and, as one of the great teachers of his time, he helped countless students over examination hurdles, and won for himself a lasting place in their admiration and esteem.—W. B. K.

C. D. GRANGE, O.B.E., M.B., B.S.
F.R.C.S.

Mr. C. D. Grange, formerly a surgeon at Harrogate and District General Hospital, died on 19 October at his home at Angmering-on-Sea, Sussex. He was 80.

Charles D'Oyly Grange, the son of a doctor, was born on 29 August 1887, and was educated at Leeds University and St. Bartholomew's Hospital, London, qualifying in 1910 with the Conjoint diploma, when he was awarded the Willett silver medal for operative surgery, and graduating M.B., B.S. two years later. After early house appointments at St. Bartholomew's Hospital he took the F.R.C.S. in 1913, and went to Newcastle upon Tyne, where he worked under Professors Morison and Grey Turner. During the first world war he served with the R.A.M.C. as major in charge of the surgical division of the Northumberland War Hospital, and was awarded the O.B.E. for his services. After demobilization he went to Harrogate, where he became surgeon to the Harrogate and District General Hospital (then known as the Harrogate Infirmary), and to the Royal Bath Hospital, Harrogate. He was also consultant surgeon to the Ripon and District Hospital. In 1932-3 he was chair-

man of the Harrogate Division of the British Medical Association. He retired in 1947.

G. N. B. writes: Grange was a versatile surgeon and a kind and charming man who endeared himself to both colleagues and patients. His juniors knew they could always rely on his help and unfailing good humour, and many of them have much to thank him for. He was a genial host, and he and his wife were well known for the warmth of their hospitality. His retirement in 1947 after many years of very hard work gave them both virtually twenty years of well-earned relaxation and happiness. To Mrs. Grange we send warmest sympathy.

E. BURSTAL, M.A., D.M.

Dr. E. Burstal, a Bournemouth general practitioner, died at his home on 12 October, at the age of 88.

Edward Burstal was born in Derby on 23 August 1879, and was educated at Dulwich College and Trinity College, Oxford, graduating B.A. In 1901 he obtained a Commoners Exhibition with honours in natural science and physiology, and for his clinical studies went to St. Bartholomew's Hospital, graduating M.B., B.Ch. in 1904. After early house appointments at St. Bartholomew's and the West London Hospital, he set up in general practice at Staines in 1909. He also held the post of assistant surgeon at the King Edward VII Hospital at Windsor. During the first world war he joined the R.A.M.C. and was major in charge of the medical division 82nd General Hospital, serving for some time in Salonika. After demobilization he proceeded D.M. in 1918, and the following year he left his practice in Staines to take up a practice at Bournemouth, in which he remained until his retirement in 1963. An active member of the British Medical Association, in 1931-2 he was chairman of the Bournemouth Division, and from 1939 to 1948 was president of the Dorset and West Hants Branch.

For recreation he was very fond of walking, especially in the Alps. He took a great interest in English numismatics, and served as president of the Wessex Numismatic Society. In 1908 he married Winifred, daughter of Worsley Battersby, who predeceased him in 1965. They had a son and two daughters.

N. F. A. writes: Dr. Burstal's death removes one more link with what may be considered as the more gracious days of living in Bournemouth, when medicine was practised at a leisurely pace and with a very personal relationship between doctor and patient. He did not value his patients at so many shillings a head—well or ill—and was essentially a family doctor, concerned almost as much with the personal as with the strictly medical problems of his patients. Though not given to suffering fools gladly, he yet possessed great charm and courtesy. He was a true general practitioner, with keen clinical judgement—rightly confident in his own ability, yet ready to seek help from colleagues when need arose. Though not prominent in medical politics, he was active in attendance at clinical and scientific meetings. He will be sorely missed for his bonhomie, clear thinking, and high standard of ethics.

V. G. BEST, M.D.

Dr. V. G. Best, formerly in general practice at Cleethorpes, Lincolnshire, died at his home in Northwood, Middlesex, on 18 July. He was 80.

Victor Greer Best was born at Ballinahinch, Co. Armagh, on 27 June 1887. He was educated at Lurgan College and at Trinity College, Dublin, graduating M.B., B.S. in 1911 and proceeding M.D. shortly afterwards. He served as ship's doctor on the Blue Funnel Line to the Far East before taking up an appointment as house-surgeon at the Grimsby and District Hospital. In 1914 he joined Dr. Walter Fisher in general practice in Cleethorpes. During the first world war he served in the R.A.M.C., and after demobilization with the rank of captain he rejoined the practice in Cleethorpes in 1918, remaining there until his retirement in 1957.

For 30 years he acted as honorary surgeon to the Cleethorpes Division of the St. John Ambulance Brigade, and was a past master of St. Albans Masonic Lodge in Grimsby. A member of the British Medical Association, he was chairman of the North Lincolnshire Division in 1925-6, and president of the Lincolnshire Branch from 1955 to 1957.

Dr. Best was respected and loved in Cleethorpes. He was a good family doctor who not only cared well for his patients but was interested in them as people; his patients were his friends, and for them nothing was too much. I joined him in the practice in 1925, and worked with him in partnership until his retirement. We worked in complete harmony; he was always good tempered, and I recall the years I worked with him with affection and pleasure.

He was a good family man, and took great joy in his daughter and her two children. To his widow, Maude, and to their family we extend our sincere sympathy.—M. C. L.

E. FRASER BROWN, M.B., CH.B.

Dr. E. Fraser Brown, formerly a general practitioner in Moseley, Birmingham, died on 18 September. He was 70.

Elliott Fraser Brown was born in Salisbury on 6 February 1897, and was educated at Monkton Combe School. He received his medical education at the University of Birmingham, qualifying with the Conjoint diploma in 1920, and graduating M.B., Ch.B. in 1924. In the first world war he saw active service as a surgeon probationer sub-lieutenant in the Royal Navy. On being invalided out he joined the First War Hospital at Rubery, Birmingham, after which he continued his training at the university. After qualification he held resident posts at the Queen's Hospital, Birmingham (now the Accident Hospital), and the Birmingham General Hospital. During the second world war he served again as a medical officer in the Royal Air Force. Dr. Fraser Brown was a family doctor in the old tradition who took a very personal interest in all his patients. He was a surgeon in the St. John Ambulance Brigade, and became county surgeon of Birmingham. He was an active member of the B.M.A. and the Christian Doctors Group.

After a life of strenuous service he was forced to retire in 1962 following a serious illness. He moved to South Devon, but still

maintained his interest in medicine, joining the local branch of the B.M.A., sitting on medical boards, and helping his local colleagues.

He will be missed by many, and the sympathy of his patients and of his many friends will go out to his widow, son, and daughter.—M. H. O.

S. S. DATTA, M.D.

Dr. S. S. Datta, for many years senior medical officer at Manor Park Hospital, Bristol, died on 3 November after a short illness. He was 77.

Sukha Sagar Datta was born in Calcutta on 23 May 1890, and came to Britain in 1910. Deciding to take up medicine, he entered Bristol University, graduating M.B., Ch.B. in 1920 and proceeding M.D. in 1931. After early appointments at Bristol General Hospital and Southmead Hospital, he was appointed resident medical officer at Stapleton Hospital (now Manor Park Hospital), where he remained until his retirement in 1956.

Dr. Datta was an active member of the St. John Ambulance Brigade, and taught first aid during and after the second world war. In 1956 he was made an Officer Brother of the Order of St. John. He was elected chairman of the Bristol Borough Labour Party in 1943 and became president of the Bristol Trades Council in 1946. After the second world war he became founder president and life member of the Bristol Indian Association, an organization to promote understanding between students and immigrants from the Subcontinent and members of the British public.

He leaves a widow and two sons, one of whom is a member of the medical profession.

D. D. writes: Dr. Datta was above all a man dedicated to the service of others; he was an idealist with a strong practical streak. He early became a follower of Freud, and after his retirement from Manor Park Hospital continued to keep abreast of post-Freudian developments in psychiatry, particularly in the fields of research in which purely chemical explanations of mental sickness are being pursued. With his death Bristol loses a very remarkable and much-loved man.

W. F. D. BENTON, M.R.C.S., L.R.C.P.

Dr. W. F. D. Benton, clinical assistant in the skin department of Croydon General Hospital, died at the hospital on 10 October after a short illness. He was 66.

William Frederick Douglas Benton, elder son of the late Dr. William Benton, was born at East Ham on 17 February 1901, and received his early education at Chatham House, Ramsgate, and Eastbourne College. For his medical studies he went to St. Bartholomew's Hospital, qualifying with the Conjoint diploma in 1926. He held appointments at Queen's Hospital, Hackney; the Albert Dock Hospital; City Hospital, Nottingham; City Hospital, Plymouth; and was ship's surgeon to s.s. *Queen of Scots*, before settling in general practice at Thornton Heath in 1934. Here he worked for 33 years, except during the second world war, when he served as captain in the R.A.M.C. in India and else-

where. At the time of his death he held the appointments of clinical assistant in the skin department, Croydon General Hospital; medical officer to Waddon Hospital, Croydon; and honorary medical officer to the British Red Cross Society.

He was a member of the local medical committee and of Croydon Executive Council. A member of the British Medical Association, he was chairman of the Croydon Division in 1955-6, and representative at the Annual Meeting in 1956, 1959, and 1962.

His hobbies were many and varied: travel, literature, and the arts, archaeology, swimming, tennis, and golf. Eleven years ago he became a member of the Roman Catholic Church. He was a man of high principles and high ideals. His colleagues and his many patients have lost a friend.

We extend our deepest sympathy to his widow, Delia, and to his brother, who is also a member of the medical profession.—C. R. N.

T. H. McLEOD, M.R.C.S., L.R.C.P.

Dr. T. H. McLeod, a well-known north Norfolk general practitioner, died suddenly on 8 October. He was 74.

Thomas Hawks McLeod, the second son of Professor Herbert McLeod, F.R.S., was born in Englefield Green, Surrey, on 5 April 1893, and was educated at Aldenham School. He studied medicine at St. George's Hospital, London, qualifying with the Conjoint diploma in 1917. He then served in the R.A.M.C. in Mesopotamia until the end of the first world war. On demobilization with the rank of captain he joined the Iraq Health Service, and continued to work in Iraq until 1935, at which time he held the post of civil surgeon, Mosul. In 1936 he came to North Walsham, Norfolk, and settled in general practice, and here he remained until his retirement in 1964. He took a great interest in the St. John Ambulance Association, and was divisional surgeon to the Order of St. John of Jerusalem.

His practice was a busy, single-handed one, and he was helped considerably by his wife, who is also a doctor. "Peter" McLeod devoted all his energies and thoughts to his patients, who held him in high regard. His interests outside his work were shooting, riding, and gardening; and during his later years what leisure time he had was spent in his beautiful garden. He was held in great esteem by his medical colleagues, who could always go to him for advice or help.

Our sympathy goes out to his widow and three children, one of whom is also a doctor.—C. D. H.

P. H. B. writes: Many people—friends, patients, and colleagues—were saddened by the sudden death of "Peter" McLeod. He and his wife, Peggy, had worked in North Walsham for so many years, and with such devotion that they had won the deepest respect and affection. This was amply shown when they retired two or three years ago to the neighbouring village of Worstead. Peter McLeod's dedication to his work left him little time for other distractions. He knew all his patients as only a doctor in a small town can, and his letters to hospital contained not only a careful history and his own clinical findings but human details which made every patient unique. He

regarded his own physical disabilities with detachment and dry humour, and with a loyal confidence in his advisers. We salute the passing of a compassionate man and a greatly loved doctor.

G. LANG, M.B., CH.B.

Dr. G. Lang, formerly in general practice at Potters Bar, Herts, died at the Holloway Sanatorium, Virginia Water, on 27 October, after a long illness. He was 61.

Gerard Lang was born on 8 November 1905, and received his medical education at the University of Edinburgh, graduating M.B., Ch.B. in 1930. After holding house appointments at Edinburgh Royal Infirmary and Leicester Royal Infirmary he settled in Potters Bar, where for over 30 years he was in partnership in general practice, retiring at the end of last year owing to ill-health. He was on the staff of the local district hospital, and was chairman of the Medical Advisory Committee. During the second world war he remained in civilian practice, accepting responsibility for the patients of other doctors on an agreed temporary basis.

He was an active member of the Enfield and Potters Bar Division of the British Medical Association and of Catholic Societies, including that of SS. Cosmas and Damian and the Guild of St. Luke. He leaves a widow and four daughters.—E. W. W. E.

D. P. THOMAS, M.R.C.S., L.R.C.P.

Dr. D. P. Thomas, a former general practitioner in Conway, Caernarvonshire, died in hospital on 18 September. He was 77.

David Page Thomas was born on 13 March 1890, and received his medical education at St. Bartholomew's Hospital, qualifying with the Conjoint diploma in 1915. Shortly after qualification he joined the R.A.M.C., and went to France. During the Battle of the Somme he was gassed, and was invalided home. Later he was posted to Palestine, where he was wounded, and after returning home he was transferred to the Ministry of Pensions Hospital in Bangor. After demobilization with the rank of captain he joined the staff of this hospital in Bangor. In 1921 he entered practice in partnership with the late Dr. M. J. Morgan in Conway. During the second world war, owing to the shortage of doctors and the large number of evacuees in the area, his work was arduous, but he gave his services throughout with courage and devotion.

I first met him in 1950 and was at once enchanted by the warmth of his personality. The better one knew him the more one appreciated his deep knowledge of medicine and his constant interest in modern trends. A skilled obstetrician, he was proud of having received his training at Queen Charlotte's. He had the gift of giving confidence to babies and young children, who always greeted him with affection. Dr. Thomas was a man of great integrity, with a deep sense of his responsibilities and an unfailing love of justice. He was a magistrate, a founder member of the Conway Rotary Club, and a Freemason, being a past master of the Royal Leek Lodge in Bangor. His sterling qualities were combined with a delightful sense of humour, and, what is perhaps rare in many of us, an ability

to laugh at himself. His conversation was always stimulating and easy. A real countryman, he took a keen interest in all country matters, and was recognized as an expert angler and marksman. He will be sadly missed in many homes in Caernarvonshire and Denbighshire, and will always be remembered as the "beloved physician."—G. H.

K. B. JONES, M.R.C.S., L.R.C.P.

Dr. K. B. Jones, who was in general practice in Sheffield, died of leukaemia on 26 July at the age of 42.

Keith Bromfield Jones was born on 28 November 1924, and qualified with the Conjoint diploma in 1951. He set up in general practice in Sheffield, and was also medical officer to several large factories and to the Sheffield College of Education, and was the appointed factory doctor to Sheffield East. He was vice-president of the Yorkshire Liberal Federation and ex-chairman of the Sheffield Liberal Party, as well as serving on the executive council of the British National Temperance League. He also did a great deal of work for the Boy Scout movement. Much of his limited spare time was spent in caravanning, of which, like everything else he took up, he was an enthusiastic supporter.

Those of us who knew Keith Jones as a colleague and neighbour remember his unfailing cheerfulness and good humour, unaffected by his dismay at the state of medicine under the N.H.S., and by his full knowledge of his disease which progressed so rapidly.

To his wife and two children we extend our deep sympathy.—G. R. B. W.

G. C. C. WHARTON, M.R.C.S., L.R.C.P.

Dr. G. C. C. Wharton, a general practitioner in Gloucester for 19 years, died on 3 September while on holiday in Norway. He was 57.

Geoffrey Charles Clegg Wharton, son of a doctor, was born in Oldham on 11 March 1910, and was educated at Malvern College, Manchester University, and Charing Cross Hospital, London, qualifying with the Conjoint diploma in 1939. After holding the post of casualty officer at Charing Cross he set out to gain experience of general practice by taking assistantships successively in Northampton, Hitchin, and Maidenhead. During the second world war he joined the Royal Air Force, and in 1946—the year after his demobilization—he became a partner in a practice in Gloucester, where he remained until 1965. At that time he felt that he could afford to resign from the National Health Service, but he greatly enjoyed clinical work, and continued to exercise his skill by assisting colleagues and in other medical work. Since 1958 he had been secretary of the local medical committee.

Geoffrey Wharton was a genial person who easily made friends. Foremost among his hobbies were golf and travelling, but he was a man of wide interests, including music, wines, antique furniture, railways, and ships. He will be remembered by all who knew him for his sense of humour, his infectious enthusiasm when talking of countries and places he had visited, and above all his happy and kindly outlook.

To his wife, Jennie, and to his two sons we tender our deepest sympathy.—H. G. D.

A. BOWIE, M.M., M.B., CH.B.

Dr. A. Bowie, a general practitioner in Newcastle upon Tyne, died on 2 October at the age of 68.

Andrew Bowie was born in Bonnybridge, Stirlingshire, on 29 October 1898, and was educated at Falkirk High School, whence he joined the 7th Black Watch, 51st Highland Division. He saw service in France during the first world war, and was awarded the Military Medal. After demobilization he entered Glasgow University, graduating M.B., Ch.B. in 1924, and went into general practice in Jarrow, Co. Durham. A year later he moved to Newcastle upon Tyne, where he remained in practice until his retirement in July 1966.

Andrew Bowie was a most human and dedicated doctor with a ready sense of humour. His home was an open door to his patients, who regarded him as a friend and counsellor. It was a privilege to work alongside a man to whom his patients' needs were of paramount importance, and who could always find time to listen to their problems.

He married in 1930, but lost his wife during the second world war after a long and tragic illness. His many friends and colleagues extend their sincere sympathy to his son and daughter, who both nursed him with great affection and courage during the last year.—G. S. A.

Sir JAMES LEARMONTH, K.C.V.O.

C.B.E., LL.D., M.D., CH.M., F.R.C.S.

F.R.C.S.ED., F.R.A.C.S., F.A.C.S.

F.R.F.P.S.GLASG.

A. W. R. writes: Sir James Learmonth's (obituary, 7 October, p. 58) students will remember him as a master of the art of teaching, a teacher without peer. His lectures, obviously prepared with scrupulous care, were delivered with clarity and conciseness, and adorned by his dexterity on the blackboard. His clinics at the bedside were models of the professional art. There was no room for levity in the presence of a sick person, and he insisted on the basic principles of politeness and respect for human dignity. On being called forward to examine a patient, woe betide the student who plunged straight into the traditional "What are you complaining of?" If he did not already know the patient's name he was instructed that a glance at the chart would provide this information. These basic principles of introduction to the medical profession were impressed on the students from the first day in his ward, and were the result of his determination to emphasize that the patient, the central important character on the stage, was a human being and not just another case. He championed the underdog, never failing to encourage the weaker student, never embarrassing him in front of his colleagues. So long as that student was industrious and doing his best, then he regarded it as his bounden duty to produce in him a sound and understanding practitioner. Teachers of the calibre of James Rognvald Learmonth are met only once in a lifetime, and those who were fortunate enough to come under his spell will remember him with gratitude and affection. He was indeed the great master with many disciples.

News and Notes

EPIDEMIOLOGY

England and Wales in Second Quarter

The abridged life table for 1964-6 in the quarterly report for June gives the expectation of life at birth for males as 68.5 years and 74.7 years for females. During the past 10 years the figures have increased by 0.9 years for males and by 1.6 years for females.

No cases of diphtheria were notified in the second quarter of 1967, but 7,053 cases of whooping-cough were notified. Measles was epidemic, with 130,190 notifications. Other large returns were 7,094 for dysentery, and 5,638 for scarlet fever. Only 6 cases of acute poliomyelitis, 5 paralytic and 1 non-paralytic, were notified. These figures are uncorrected.

The rising trend of emigration to Australia, Canada, and New Zealand continued. The numbers rose from 28,700 persons in the second quarter of 1964 to 43,100 persons in the second quarter of 1967 (Australia 25,600, Canada 13,100, and New Zealand 4,400). In the professional and managerial category the numbers of emigrants rose and those of immigrants fell in comparison with the previous second quarter, giving an estimated loss of 3,000 in the first quarter of 1967 compared with a net gain of 200 in the corresponding quarter of 1966.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of scarlet fever and whooping-cough in England and Wales.

Figures for 1967 are compared with the highest and lowest figures for each week in the previous years shown.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending 28 October (No. 43) and corresponding week 1966.

Figures of cases are for the countries shown and for Greater London. Figures of deaths and births are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Smallpox at Wandsworth

The Medical Officer of Health for the London borough of Wandsworth has sent us the following report on a case of smallpox there:

"On the evening of 16 October a 3-year-old Pakistani girl, recently arrived in this country, was seen in the receiving-room at St. George's Hospital, Tooting, and clinically diagnosed as a case of smallpox.

"The duty doctor notified his consultant physician and subsequently the medical officer of health, and in the early hours of the following morning the child, together with her mother, was admitted to Long Reach Isolation Hospital, Dartford, smallpox having been confirmed by the gel-diffusion test. The mother subsequently developed several small skin lesions from which smallpox virus was grown. She had no constitutional disturbance and her condition was regarded as a highly modified form of smallpox.

"On 20 October the father of the child was also admitted to Long Reach after having become pyrexial. No skin lesions developed and the pyrexia subsequently settled and smallpox has not been confirmed. The little girl is now recovering and both parents are well. Surveillance of contacts in Wandsworth has not so far revealed any further cases."

PARLIAMENT**Ministerial Assurances on Artificial Sweeteners**

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The argument for deferring the permissive use of artificial sweeteners was answered by the Parliamentary Secretary to the Ministry of Agriculture, Fisheries and Food, Mr. J. HOY, in the House of Commons on 9 November.

Use in all foodstuffs except ice-cream is permitted by the Artificial Sweeteners in Food Regulations, which come into force on 1 December. Mrs. JOYCE BUTLER (Wood Green, Lab.) sought to annul the regulations and have the use of cyclamates deferred until further studies were completed.

Mr. Hoy, taking seriatim the objections which were raised in the debate, said the simple answer about the exclusion of ice-cream from the regulations was that artificial sweeteners were forbidden in the ice-cream regulations, 1959; it was part of the compositional requirements and had nothing to do with the safety of cyclamates or saccharin. It was not true that the European Economic Commission had decided that cyclamates had not to be used. All that had been decided was that they would delay harmonization. Four countries would continue to use them, as they were doing now. There had been no announcement that the Food and Drugs Administration in the United States was doing further work on cyclamates, except in the normal process of their work. In this country the Food Additives and Contaminants Committee's recommendation for further work was a common recommendation for all types of additives; it was what was normally done to keep the Government aware of what was happening on a continuous basis.

Mr. Hoy assured the House, on the advice of the Ministry specialists, that cyclohexylamine was not a cancer-causing agent. M.P.s, he said, should not use terms which frightened people. Dicyclohexylamine did not metabolize from cyclohexylamine; it had been looked for but had not been found.

Specifications were laid down in the regulations by reference for the various types of cyclamate, and also—for the first time—for the various types of saccharin. A minimum content of saccharin and cyclamate respectively was laid down for mixed tablets.

Since fresh evidence about the safety of cyclamates was submitted, the question of their use had been twice referred back to the Food Additives and Contaminants Committee. Both reports from the committee recommended that there was no hazard to health in permitting the use of cyclamates—conforming to satisfactory specifications—in food. Since the advice of the Government's experts had been almost exactly echoed by that of the Joint Expert Committee of the Food and Agriculture Organization and of the World Health Organization, the Government were on fairly safe ground.

The use of cyclamates was likely to be limited. They would chiefly be employed with sugar or saccharin? Apart from soft drinks—in which they had been permitted since 1965—their main use was likely to be in canned fruit and vegetables, jellies, pickles and sauces, and some types of sweet confectionery. To people who must avoid too much sugar cyclamates would be of great benefit and would greatly improve the attractiveness of food, particularly cooked food. They represented a technical advance, and the experts were satisfied there was no health risk.

The motion to annul the regulations was withdrawn.

Accidents in Industry

Dr. SHIRLEY SUMMERSKILL (Halifax, Lab.) asked the Minister of Labour on 13 November what steps he was taking to reduce the increasing number of industrial accidents and deaths.

Mr. R. GUNTER stated that he had recently

appointed the Industrial Safety Advisory Council, both to advise him on measures to be taken centrally and to encourage and co-ordinate action throughout industry to promote safety. Priority was being given to work on safety training in close co-operation with the machinery set up under the Industrial Training Act; joint consultation on safety; research needs and the improvement of statistical information as a basis for action.

Government financial support was being given to the work of the regional organization for industrial safety of the Royal Society for the Prevention of Accidents.

Legal requirements were continuously under review, and within recent months a start had been made on a major revision of the safety, health, and welfare legislation for which he was responsible. In addition, steps were being taken to increase the strength of H.M. Factory Inspectorate.

"While legislation and enforcement have an important part to play in accident prevention," he said, "there will only be an effective reduction in the number of accidents if managements and employees fully understand and accept their own responsibilities."

Immigrant Medical Staffs

Sir DAVID RENTON (Huntingdonshire, Nat. Lib. and Con.) asked the Minister of Health how many Commonwealth immigrants and aliens, respectively, were employed in hospitals, maternity homes, and similar establishments in England and Wales as doctors, nurses, and student nurses, respectively, on the latest date for which figures are available. Mr. K. ROBINSON stated that at 30 September 1965 there were about 6,150 doctors, other than locums, holding posts in National Health Service hospitals, who were born outside the United Kingdom and the Irish Republic. This represented about 30% of the total. More detailed information about doctors was not available.

MEDICAL NEWS

Royal Society Medals

The Copley medal has been awarded to Professor B. KATZ, F.R.S., professor of biophysics at University College, London, for contributions to knowledge of the fundamental processes involved in transmission across the neuromuscular junction.

The Buchanan medal has been awarded to Sir GRAHAM WILSON, director of the Public Health Laboratory Service of England and Wales from 1941 to 1963, for work on the medical aspects of bacteriology and immunity and for the Public Health Laboratory Service.

Appointment to Professorship

The title of professor of clinical immunology has been conferred on Dr. J. PEPYS in respect of his post at the Institute of Diseases of the Chest. Professor Pepys graduated at the University of Witwatersrand in 1935. Coming to England in 1948, he held appointments at the Royal National Ear, Nose, and Throat Hospital, the department of pathology of Guy's Hospital, and the Wright-Fleming Institute, St. Mary's Hos-

[W. Churcher]

pital. In 1955 he was appointed senior lecturer, and in 1964 reader in clinical immunology at the Institute of Diseases of the Chest. He is honorary consultant in clinical immunology to the Brompton Hospital. From 1960 to 1967 he was director of the M.R.C. Research Group in Clinical Immunology at the Institute. His research activities during this time have concerned reactions to inhaled organic dusts. The elucidation of the antigen-antibody reactions underlying farmer's lung and the identification of thermophilic actinomycetes as the source of the antigens led him to the study of other diseases resembling farmer's lung, in that similar reactions to inhaled organic dusts were occurring in the gas-exchanging part of the lung. He has also contributed to knowledge of the immunological basis of diseases associated with the common mould *Aspergillus*. These studies have involved a general interest in precipitin-mediated hypersensitivity reactions in man. His earlier interests included the mechanism of the tuberculin reaction.

Academic Posts in Psychiatry

In 11 medical schools, including Oxford and Cambridge, there is no professorial department of psychiatry, said Sir GEOFFREY VICKERS in the annual address last week to the Mental Health Research Fund. Sir Geoffrey, a former treasurer of the Medical Research Council, retired this year as chairman of the fund's research committee. In medicine generally, he said, professors and medical teachers numbered over 1,500, of whom 450 were professors. The corresponding numbers for psychiatry were 80 and 20. "There are more than six academic posts for

every 100 doctors in the hospital service, less than four for every 100 psychiatrists; more than two professors for every 100 doctors but less than one for every 100 psychiatrists." Sir Geoffrey stressed three basic needs: to create more established posts in the academic departments; to increase, both within and outside the universities, the posts in which research is the main responsibility; and to expose medical students and young doctors to more psychiatry and psychiatric research before they take their first registrarship.

Centre for Postgraduate Medical Students

The Lister Institute of Postgraduate Medical Education and Research was opened in Edinburgh last week by LADY FRASER, wife of the late Sir JOHN FRASER, a former principal of Edinburgh University. It provides teaching accommodation and completes the development of the postgraduate education complex. The first stage was the Pfizer Foundation building, opened in July 1965 (see *B.M.J.*, 17 July, p. 179). LORD FLOREY, O.M., F.R.S., delivered the Lister Oration.

Commonwealth Fund

The 1967 report of the Commonwealth Fund records a grant of \$534,800 to Oxford University faculty of medicine to help to finance the construction and equipping of a clinical sciences instructional laboratory and the addition of academic and technical staff. Commenting on the University's reform of education, the report says that the new curriculum when fully implemented will represent "a model of strong university commitment to medical learning" and will have considerable application to problems of United States and Canadian medical schools. During the year ended 30 June Harkness fellowships were awarded to 26 candidates in the United Kingdom, three in the medical and biological sciences.

Early Diagnosis and Surveillance

The Office of Health Economics is sponsoring a series of pamphlets on the early diagnosis and surveillance of disease, written with the general practitioner especially in mind. The first two pamphlets are now available, price 2s. 6d. each from the Office, at 162 Regent Street, London W.1. Their titles and authors are *The Early Diagnosis of Raised Arterial Blood Pressure*, by Dr. W. W. HOLLAND, and *The Early Diagnosis of Visual Defects*, by Mr. P. A. GRAHAM.

Multiple Screening Clinic

From 21 November to 1 December a multiple screening programme will be carried out at Rotherham (see *B.M.J.*, 1965, 30 October, p. 1034). This year's clinic has 10 test stations, eight of which are suitable for men and eight for women. The tests will cover blood and urine, arteries and heart, chest x-ray, lung function, breast and cervical cancer, vision, glaucoma, and mental health. There will be no open sessions, the tests being taken by appointment.

Hospital Research Project

An investigation into the organization and administration of hospitals and the hospital service is to be undertaken during the next three years by the School of Social Sciences at Brunel University. It forms part of the hospital efficiency programme of research

sponsored by the Ministry of Health, and will be conducted in collaboration with regional hospital boards and other units of hospital administration. Mr. MAURICE KOGAN, formerly secretary to the Central Advisory Council for Education, has been appointed director of the project, which will be under the general supervision of Professor ELLIOTT JAKES. The research team will be assisted by appropriate departments of the university.

Oncologists Association

The Association of Head and Neck Oncologists of Great Britain has been formed to make contributions to the progress of all aspects of oncology relating to the head and neck by research into and discussion of medical, surgical, radiotherapeutic, pathological, chemotherapeutic, and other problems. Membership of the association is open to those interested in head and neck oncology. Further details and forms of membership will be supplied on application to Mr. R. W. RAVEN (chairman, steering committee), Department of Surgery, Royal Marsden Hospital, Fulham Road, London S.W.3.

Casualty Surgeons Association

After the meeting of senior casualty officers at Luton in March a committee was nominated which met in London on 12 October and formally established the Casualty Surgeons Association. The following were elected officers: *president*, Mr. M. ELLIS; *secretary*, Mr. E. P. ABSON; *treasurer*, Dr. D. B. HINDLE.

British Computer Society

The medical specialist group of the British Computer Society, which was launched about a year ago, holds meetings every six weeks from October to July at the Hospital Centre in London. Inquiries should be sent to Dr. J. M. FORSYTHE, chairman of the group. His address is 1A Sandy Road, Norton, Stourbridge, Worcestershire.

Nutrition of the Elderly

A survey of nutrition of the elderly in the Rutherglen area, Lanarkshire, is to be conducted by Professor W. FERGUSON ANDERSON, of the David Cargill chair of geriatric medicine at Glasgow University. The aim of the project, which will be based on random sampling, is to find out whether old people are getting enough food, and food of the right type, to maintain health. The Ministry of Health, jointly with the Scottish Home and Health Department, will cover the cost of the survey up to £1,500.

Doctor Appointed Managing Director

Dr. G. E. PAGET has been appointed managing director of Smith Kline and French Laboratories in Britain. He succeeds Mr. STANLEY FENWICK, who is taking up an appointment with the parent company in Philadelphia, U.S.A. Dr. Paget, who is 45, graduated at Durham in 1944 and proceeded M.D. in 1954. He was lecturer in pathology at Manchester University before going to the pharmaceuticals division of Imperial Chemical Industries, where he was head of the section of pathology. In 1963 he joined Smith Kline and French Laboratories as director of research and development.

Awards Scheme for Overseas Students

A new scheme of awards for students from the developing countries, with effect from the academic year 1968-9, was announced in the Commons on 9 November by Mr. R. PRENTICE, Minister of Overseas Development. The awards, he said, would be for fees at universities and other institutions but not maintenance or travel or other costs. They would be held for an average period of two years. He expected about 1,000 students a year would qualify; when the scheme was in operation it might cover about 2,000 students in Britain. The cost would be approximately £500,000 in a full year.

People in the News

► Mr. CYRIL ROBERTS, former member of the National Coal Board responsible for staff, has been appointed chairman of the Institute of Cardiology.

► Mr. JOHN A. LUMLEY, chairman and managing director of Riker Laboratories, has been elected president of the Association of the British Pharmaceutical Industry.

News in Brief

A second training centre for young adult spastics has been completed by the Spastics society at Slydales Road, Lancaster. The Society's first training centre, Sherrards, at Welwyn, Hertfordshire, was opened in 1957.

The Standing Technical Committee on Synthetic Detergents has reported to the Minister of Housing and Local Government (Ninth Progress Report, H.M.S.O., 2s.) that the quantity of detergents in sewage effluents and rivers has been reduced by two-thirds since the change-over to soft detergent material—that is, material more easily decomposed in water. The search for even softer materials is to continue.

Recent Publications

A new handbook *Pneumoconiosis and Allied Occupational Chest Diseases*, with a foreword by the chief medical officer of the Ministry of Social Security, replaces previous publications of the Ministry on the subject. There is a section on the work of the pneumoconiosis panels. H.M.S.O., 3s. 3d. net.

Clean Air Act 1956: *Chimney Heights*. This is a revised edition of the memorandum published in 1963. H.M.S.O., 2s. 6d.

Everybody's Guide to Social Security, with a foreword by Mrs. JUDITH HART, Minister of Social Security. H.M.S.O., 1s. (postage 4d.).

A hospital admission leaflet for parents has been prepared by the National Association for the Welfare of Children in Hospital (74 Denison House, 296 Vauxhall Bridge Road, London S.W.1). Single copies 1s. 6d. post free.

Preparation for Retirement is the first brochure in a health education series published

for the Medical Association of South Africa by the *South African Medical Journal*.

Coming Events

Postgraduate Medicine, 1967 (T.V. Programme).—"Advances in Reconstructive Surgery," Scottish Television, 20 November (11.50 p.m.), repeat 22 November (1.10 p.m.). "Advances in Cardiology," Tyne Tees Television, 21 November (1.15 p.m.), repeat 26 November (10.15 a.m.).

College of Pathologists.—At Royal College of Physicians of London, 22 November, 11 a.m., annual general meeting; 5.45 p.m., Foundation lecture, "Immuno-pathology," by Professor R. R. A. COOMBS, F.R.S. (admission free without ticket); 7 for 7.30 p.m., annual dinner.

Royal Marsden Hospital.—Centenary open day, 22 November. Details from Mr. T. WEST, Lonsdale Information Ltd., Commonwealth House, London W.C.1.

Medical Society for the Study of Venereal Diseases.—Meeting, "General Infection in Women," 24 November, 7 p.m. for 7.30 p.m., 11 Chandos Street, London W.1.

Medical Association for the Prevention of War.—Symposium (jointly with Conflict Research Society), "The Politics of Research into Peace and War," 25 November, 10 a.m., Gustave Tuck Theatre, University College London, Gower Street, London W.C.1.

Royal Society of Medicine.—Lloyd Roberts lecture by Baroness Wootton, "Crime and the British Penal System—Reflections of a Long-service Magistrate," 30 November, 6 p.m. Admission without ticket.

Institution of Electrical Engineers.—Faraday Lecture, "Medical Electronics," by Dr. D. W. HILL, 30 November, 6 p.m., Central Hall, Westminster. Admission free. Applications for tickets to Secretary (Dept. LC), Institution of Electrical Engineers, Savoy Place, London W.C.2.

Newcastle upon Tyne University in conjunction with Royal College of General Practitioners (North-east England Faculty).—Symposium, "Sex Problems and Contraception," 3 December, in Newcastle. Details from Postgraduate Sub-dean, The Medical School, The University, Newcastle upon Tyne 1.

Kent Postgraduate Medical Centre at Canterbury.—Conference, "Brucellosis," 3 December, 2 p.m., Kent and Canterbury Hospital. Details from Mr. M. D. KAY at the hospital.

Worshipful Society of Apothecaries of London.—350th anniversary of the foundation of the Society, 6 December. Celebrations, 3 to 8 December, include a symposium, "Medicine and the City of London (1617-1967)," 5 December, in the Great Hall of St. Bartholomew's Hospital.

King Edward's Hospital Fund for London.—Conference, "The Patient in the Community—Co-ordination Examined," 5 December, Hospital Centre, 24 Nutford Place, London W.1. Applications by 27 November.

Lister Commemoration.—Symposium, "Operating Rooms a Century After Lister," arranged by the British Medical Association, 8 December, 2 p.m., B.M.A. House. The Minister of Health will open the symposium. There will be an exhibition of modern theatre designs, also a portable operating theatre. Admission by programme obtainable from the Secretary, British Medical Association, B.M.A. House, Tavistock Square, London W.C.1.

Institute of Urology.—Week-end course on "Recent Advances in Urology," 8-10 December. For details see advertisement on p. xxxiii.

British Society of Audiology.—Meeting, 8 December, 2 p.m., Department of Audiology and Education of the Deaf, Manchester University. Programme will consist of lecture demonstrations. Details from Mr. A. BOOTHROYD, Department of Audiology, Manchester University.

Biochemical Society.—Joint meeting with Society for General Microbiology, 14-15 December, Leicester University. The programme will include a symposium on "Control of Gene Function in Micro-organisms." Details from Executive Secretary, Biochemical Society, 7 Warwick Court, Holborn, London W.C.1.

Glasgow Postgraduate Medical Board.—The programme for 1967-8 is available. Details of courses can be obtained from Professor C. M. FLEMING, Director of Postgraduate Medical Education, The University, Glasgow W.2.

Societies and Lectures

For attending lectures marked Ⓢ a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Monday, 20 November

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 5.30 p.m., clinical meeting.
HUNTERIAN SOCIETY.—At Apothecaries' Hall, 8.30 p.m., "Fee for all is better than Free for all."
INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. A. Jarrett: Process of Keratinization.
INSTITUTE OF DISEASES OF THE CHEST.—6.15 p.m., Dr. K. B. Jefferson: Radiology of Coronary Artery Disease.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., combined staff consultation clinical meeting

New Issues of Specialist Journals

Obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London W.C.1.

ABSTRACTS OF WORLD MEDICINE

The November issue (Volume 41, No. 11) contains, as well as abstracts of papers from current world medical literature, a review article entitled

Clinical Aspects of Diabetes Mellitus

By M. G. Fitzgerald, M.D., M.R.C.P.

A wealth of current thinking has been assembled in this authoritative article on a subject which is of continuing interest and importance. Sections deal with factors predisposing to diabetes, atherosclerosis and diabetes, diabetic retinopathy, nephropathy and neuropathy, coma in the absence of ketoacidosis, treatment with the newer insulins, the sulphonylureas, and the diuretics, and finally insulin antagonism. There is an extensive bibliography for those who wish to pursue the subject still further.

Published monthly Annual subscription £6 6s., U.S.A. \$18. Single number 12s. 6d.

KINGSTON-UPON-THAMES MEDICAL CENTRE.—5.15 p.m., Dr. B. Cheng: Basic Genetics; 6.30 p.m., Dr. P. Flute: Fibrinolysis. ●
LEEDS AND WEST RIDING MEDICO-LEGAL SOCIETY.—At Clinical Theatre, General Infirmary at Leeds, 8.30 p.m., speaker, Lord Merthyr.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Heath Clark lecture on perspectives in health planning—III by Dr. A. Engel (Sweden): Mass Screening for Asymptomatic Disease as a Public Health Measure.
ROYAL FREE HOSPITAL.—5.15 p.m., Dr. Barbara Evans: A Visit to South Vietnam.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Dr. Stuart Mason: Epidemiology of Addison's Disease.
SCOTTISH TELEVISION LTD.—11.45 p.m., Advances in Transplant Surgery. (Sponsored by Glasgow Postgraduate Medical Board.)

Tuesday, 21 November

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Dr. F. H. Doyle: Radiological Measurements in Endocrine and Metabolic Diseases.
INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. M. Feivel: The Skin and the Adrenals.
INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Hammersmith Hospital, 3 p.m., Dr. J. Insley: Chromosomal Abnormalities in Gynaecological Practice. ●
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Heath Clark lecture on perspectives in health planning—IV by Dr. A. Engel (Sweden): The Swedish Regionalized Hospital and Health System.
NEATH POSTGRADUATE MEDICAL CENTRE.—At Neath General Hospital, 4 p.m., Mr. D. K. Sambrook: My Recent Visit to the United States.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Professor R. B. Welbourn: Cushing's Syndrome.
SOCIETY OF APOTHECARIES OF LONDON: FACULTY OF THE HISTORY OF MEDICINE AND PHARMACY.—5.30 p.m., Sydenham lecture by Professor C. D. O'Malley: John Evelyn and Medicine. ●
SURREY UNIVERSITY.—At Great Hall, 5.30 p.m., Professor J. Waterlow: The Body's Need for Protein—a Challenge for Research.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. N. G. Hulbert: clinical demonstration.
WESTMINSTER MEDICAL SCHOOL.—At Keene Theatre, 5.15 p.m., Dr. J. D. Swales: Observations on Renal Hypertension.

Wednesday, 22 November

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 12 noon, surgical meeting.
INSTITUTE OF DERMATOLOGY.—4.30 p.m., Professor F. A. Whitlock: Psychosomatic Disease—I.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. H. Scadding: Management of Patients with Asthma.
INSTITUTE OF NEUROLOGY.—6 p.m., Dr. A. M. Jelliffe, and 7 p.m., Dr. P. T. Lascelles: The Use and Misuse of Ionizing Radiation in Neurology.
INSTITUTE OF UROLOGY.—5 p.m., Mr. J. E. A. Wickham: Surgery of Renal Calculi.
MANCHESTER MEDICAL SOCIETY.—At Large Anatomy Theatre, Manchester University Medical School, 4.30 p.m., Telford memorial lecture by Professor E. B. Chain, F.R.S.: Recent Developments in Bacterial Chemotherapy.
OXFORD UNIVERSITY MEDICAL SCHOOL.—At Nuffield Maternity Home Lecture Theatre, Radcliffe Infirmary, 5 p.m., Dr. J. Chayen: Measurement of Metabolic Function in Biopsies.
ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—5.30 p.m., postgraduate museum demonstration by Mr. J. B. Blakley: A Surgeon's Comments on the Pathology of Carcinoma of the Cervix Uteri.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 11.45 a.m., clinicopathological conferences by Professor R. Fraser: Renal Failure; Dr. E. D. Williams: Hyperparathyroidism. (2) 2 p.m., Professor J. A. Strong: Obesity.
SCOTTISH TELEVISION LTD.—1 p.m., Advances in Transplant Surgery. (Sponsored by Glasgow Postgraduate Medical Board.)
STOKES MANDEVILLE HOSPITAL.—(1) 12.15 p.m., Dr. C. S. Pitcher: clinical cases. (2) 6 p.m., Air Vice-Marshal W. P. Stamm: Amoebiasis.
WEST MIDDLESEX HOSPITAL.—At Lecture Theatre, 5 p.m., Dr. J. Marshall: Dementia as a Presenting Symptom.

Thursday, 23 November

ABERDEEN UNIVERSITY FACULTY OF MEDICINE.—At Large Lecture Theatre, University Medical Buildings, Foresterhill, 5 p.m., Professor D. D. Reid: International Studies in Cardio-respiratory Disease.
BIRMINGHAM UNIVERSITY MEDICAL SOCIETY.—At Medical School, 5.15 p.m., B.M.A. lecture by Professor D. A. K. Black: "Life With and Without Kidneys".
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Dr. H. K. Weinreb: Control of Growth and Regeneration in the Liver.
DUNDEE UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Professor H. C. Miller

(Kansas): Psycho-Biological Approach to Problems of the Newborn.
INSTITUTE OF DERMATOLOGY.—4.30 p.m., Dr. J. S. Pegum: Apocrine Glands.
LEAMINGTON MEDICAL SOCIETY.—At Warneford Hospital, 8.30 p.m., Mr. M. P. Ward: Man at High Altitude—Mountain Physiology.
LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8.30 p.m., Dr. Letitia Fairfield: Pioneer Medicine.
NORTHAMPTON GENERAL HOSPITAL.—12.30 p.m., Dr. J. J. Walsh: Domestic Resettlement of Tetraplegics and Paraplegics.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Professor J. V. Dacie: Recent Advances in the Knowledge of Haemolytic Anaemias.
ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 4 p.m., Dr. D. G. Melrose: Heart Lung Machines. (2) 5 p.m., lecture on medical history by Dr. E. S. Clarke: The Anatomical Basis of Medicine—II.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright Fleming Institute Theatre, 5 p.m., Aleck Bourne lecture by Mr. V. R. Tindall: Thromboembolism in Obstetrics and Gynaecology.

Friday, 24 November

BROOK GENERAL HOSPITAL.—(1) 2 p.m., clinical cases by Dr. W. E. Mahon. (2) 5.30 p.m., Dr. W. Tillman: Use of Steroids in Dermatology.
KINGSTON-UPON-THAMES MEDICAL CENTRE.—At gynaecological outpatients department, Kingston Hospital, 2.30 p.m., medical case demonstration.
ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—At Nuffield Hall of the College, (1) 3.30 p.m., William Blair-Bell memorial lecture by Miss E. Blanche Butler: Effect of Iron and Folic Acid on Red Cell and Plasma Volume in Pregnancy; (2) 5 p.m., J. Y. Simpson oration by Mr. A. Gunn: James Young Simpson, the Complete Gynaecologist. ●
ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Dr. G. A. Rose: Some Aspects of Osteoporosis.
WEST MIDDLESEX HOSPITAL.—4 p.m., Professor P. Huntingford: Early Detection of Foetal Distress.

Appointments

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—Enid C. Evans, O.B.E., M.R.C.S. (honorary curator, Museum of Pathology at the Medical Academic Unit, Chelmsford).
GRAHAM, N. G., M.B., F.R.C.S., F.R.A.C.S. (consultant general surgeon to the Huddersfield Royal Infirmary and associated hospitals).
MANCHESTER REGIONAL HOSPITAL BOARD.—V. D. Dalal, M.B., F.R.C.S. (whole-time or maximum part-time consultant traumatic and orthopaedic surgeon, Rochdale and District group of hospitals); D. McIntyre, M.B., F.R.C.S. (whole-time or maximum part-time consultant urologist, at the Salford Royal Hospital, Crumpsall Hospital, Manchester, and the Royal Manchester Children's Hospital, Pendlebury); N. MacDonald, M.B., F.R.C.S. (whole-time or maximum part-time consultant surgeon, Wythenshawe Hospital, Manchester); Maira P. Jonas, M.B., D.P.M. (whole-time or maximum part-time consultant child psychiatrist, Bolton and District and Wigan and Leigh groups of hospitals).
MINISTRY OF OVERSEAS DEVELOPMENT.—Sheila A. Benningfield, M.B., M.R.C.P., D.C.H. (registrar, Children's Hospital, Saigon).
NORTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—J. H. Baron, D.M., M.R.C.P. (consultant physician in general medicine to Tottenham group of hospitals); A. F. Davy, M.R.C.S. (medical assistant in accident and orthopaedic surgery at St. Helena group of hospitals); H. W. G. Loudon, M.B. (consultant chest physician to Ilford and District group of hospitals); Margaret H. Tripp, M.B., D.P.M. (medical assistant with special interest in drug addiction at St. Clement's Hospital).
NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—Bridget A. Jepson, M.B., F.F.A.R.C.S. (consultant anaesthetist at Wilkesden General Hospital); F. G. Ellis, M.S., F.R.C.S. (consultant surgeon at Royal Northern Hospital); A. D. Atkinson, M.B. (assistant geriatrician (medical assistant grade) to the Hillingdon group and Harefield and Northwood group of hospitals); G. Snape, M.B., D.P.M. and R. Ravden M.B., D.P.M. (assistant psychiatrists (medical assistant grade) at Shenley Hospital); N. J. Doherty, M.D., M.R.C.P., D.C.H. (consultant paediatrician at West Middlesex, Ashford, Hounslow, and South Middlesex Hospitals); I. D. Archibald, L.R.C.P.S. & Sd. (assistant surgeon (medical assistant grade) in traumatic and orthopaedic surgery at West Middlesex Hospital); Sybil M. Cockersell, M.R.C.S. (assistant in Accident/Emergency Department (medical assistant grade) at Watford General Hospital (Peace Memorial Wing)); M. F. Stranc, F.R.C.S. (consultant plastic surgeon at West Middlesex, Hillingdon, Wexham Park and Mount Vernon Hospitals); J. W. Blandland, M.B. F.R.C.S. (consultant general surgeon to the Windsor group of hospitals); Bridget A. Jepson, M.B. F.F.A.R.C.S. (consultant anaesthetist at Royal Northern and City of London Maternity Hospitals); E. W. G. Davies, M.B., F.R.C.S. D.O.M.S. (consultant ophthalmologist at West Middlesex, South Middlesex, and Teddington Memorial Hospitals); Md. M. Ali, L.M.S.S.A.,

D.O. (assistant ophthalmologist (medical assistant grade) at Edgware General Hospital and School Eye Clinics).

Universities and Colleges

ROYAL COLLEGE OF PHYSICIANS OF LONDON

On 1 November the following candidates, having satisfied the Censors' Board, were admitted Members of the College:

B. D. Apthorp, B. M. O. Arbab, N. Arumugam, J. T. Baker, D. B. Bannerjee, J. B. G. Benedikt, A. Bernstein, M. Black, A. A. D. Blair, J. A. Blankson, P. R. Bradley-Moore, I. D. L. Brewis, D. A. Canavan, J. Candy, W. R. Chapman, J. A. Child, Barbara A. Clarkson, S. B. Cohen, A. E. Collins, G. O. Cowan, B. R. M. Crook, L. R. Da Costa, A. J. David, B. Davies, P. A. Du Plessis, M. C. Dutta, J. U. Egere, R. S. Elkeles, Anne G. Ferguson, N. D. C. Finlayson, L. M. Flacks, O. J. Follows, P. H. Frank, C. C. Frears, J. S. Geddes, A. L. Gibson, C. Godber, D. P. B. Goldberg, P. L. Golding, T. J. Goodwin, A. McL. Gordon, M. A. Halim, I. W. F. Hanham, A. M. M. Haq, A. Ul Haq, H. Harris, J. B. Hawkins, H. J. Heggarty, R. C. Hickman, M. T. Hossain, Florence A. Howell, R. C. Hughes, K. R. Hunter, Elizabeth R. K. Imrie, K. J. Ivey, P. C. Jain, V. K. Jayaram, S. R. Jayasuriya, D. M. Johnston, G. Jones, B. R. Kanyerezi, D. L. Kennard, S. Kumar, G. N. Kundaje, L. C. Lau, D. McCall, G. P. McMullin, W. J. McNeilly, A. P. Manasse, A. R. Marsh, J. C. Marshall, B. Mason, J. D. Maxwell, S. C. D. Mehta, A. B. Monro, W. R. Moore, A. G. Morgan, S. K. Mukherjee, Janet Murray, P. C. H. Newbold, Charnian R. Newton, S. H. Ng, A. C. Nigam, M. Perlman, J. O. M. Pobe, R. Rao, M. P. Ravindranathan, Pamela A. M. Rendell, J. F. Rivers, A. Robinson, M. J. Rose, Alison Ross, P. R. Salmon, N. K. P. Singh, D. C. Sinha, B. N. Somayaji, B. W. Somerville, J. B. Stoker, R. W. Stout, W. Warren, R. L. Willing, A. C. MacD. Windsor, D. L. Wingate, G. Withers, P. F. M. Wrigley, V. Wynn, D. W. Young, F. Q. Uz Zaman, H. Zeitlin.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council held on 9 November, with Sir Hedley Atkins, president, in the chair, Professor J. F. Nunn was admitted to the Board of Examiners for the Fellowship in the Faculty of Anaesthetists.

A resolution of condolence was passed on the death of Mr. L. E. C. Norbury (past member of Council and vice-president).

The Hallett prize for 1966 was presented to Dr. Omer Mohamed Beilel (University of Khartoum).

Handcock prizes were presented to Dr. P. J. Leopard (Guy's Hospital Medical School) and Dr. R. T. Watson (St. Thomas's Hospital Medical School and Macloghlin scholar 1961).

The appointment of Dr. G. B. Arden (Institute of Ophthalmology) as the Edridge Green lecturer for 1967 was reported.

The Begley prize was awarded to Dr. M. M. Bowen (St. Bartholomew's Hospital Medical College).

The award of the Nuffield prize to Dr. Jennifer A. Jones was reported.

The appointment of Dr. J. D. Robertson as Frederic Hewitt lecturer for 1969 was reported.

Diplomas of Membership were granted to P. S. Bennett, R. C. Bucknall, I. M. Hutton, and F. T. S. Loh.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: *Atiology*, London W.C.1. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.

ADVERTISEMENTS AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY 25 NOVEMBER 1967

Pointers

Advancement of Learning: Lord Platt voices some salutary home truths about clinical research and warns against trying to prove everything by contrived experiments (p. 439). Leader this page.

Relieving Infertility: Clomiphene therapy is more efficacious in patients with amenorrhoea of short duration who have normal-sized ovaries (p. 444). Similar findings reported in large series from Israel (p. 446). Leader at page 434.

Porphyria in Sweden: Variegata type in three families totally unrelated to families with sufferers from acute porphyria intermittens (p. 449).

Peanuts and Bleeding: Controlled study does not bear out clinical impression that haemophiliacs have fewer bleeding episodes on diet which includes peanut extracts (p. 453).

Gastric Acid Secretion: Pentagastrin may supersede histamine in testing for complete vagotomy as results are comparable and side-effects minimal (p. 456).

Effects of Cold Storage: Red cells and intracellular enzymes appear to survive five years at minus 196° C. satisfactorily (p. 458).

Haemorrhagic Enterocolitis: Association with heart failure, rather than with disease of splanchnic vessels, is postulated, and condition may be precipitated in certain climatic conditions by proliferation of normally harmless organisms in the bowel (p. 460).

Case Reports: Prevention of traumatic Bell's palsy (p. 464). Sarcoid myopathy improved with corticosteroids (p. 465). Transfusion malaria (p. 466).

Postgastrectomy Syndrome: Concluding the review of complications (p. 467).

Clinicopathological Conference: Cushing's syndrome with misleading urinary steroids (p. 472).

Employing the Computer: Inpatient statistics more accurately derived by taking the person rather than the hospital discharge as the unit (p. 476).

Television Medicine: Role of television in medical education discussed at B.M.A. lecture (p. 479).

Hospital Administration: Functions of hospital boards and their composition questioned in first letter (p. 482).

Christmas Cards: Christmas cards purchasable from B.M.A. House: profits to medical charities (p. 490).

Public Health Medical Officers: Firm offer received in response to salary claim (*Supplement*, p. 58).

Cui Bono?

William Harvey was by contemporary accounts a brilliant scientist but an indifferent medical practitioner. The antithesis is not altogether unexpected, because the cool, objective approach to ideas and hypotheses—the scientific method—is not always compatible with the emotional involvement of caring for sick people. Until recently a doctor could choose between laboratory and clinical practice, but with increasing technological advance and emphasis on man as the most suitable experimental model in which to study the effects of disease the division between scientist and practitioner has become blurred. The medical profession is thus faced with a new dilemma—the need to preserve human dignity while ensuring that medical advance is not retarded. Its manifestations have not gone unnoticed. Hospitals have been attacked for alleged indignities to patients used for teaching purposes, and research institutions have been accused in a celebrated *exposé* of carrying out questionable experiments on human patients. Doctors would be less than human if they did not attempt to minimize these criticisms as rare exceptions to the general rule of high ethical standards. But when a former professor of medicine and member of the medical establishment voices similar doubts about the path along which academic medicine is travelling our attitudes towards the role of scientific research and teaching must be re-examined.

Lord Platt, in his Harveian oration, which we print at p. 439, accepts that the application of the scientific method has brought much benefit to the investigation of bodily function and of disease. But he points out that academic clinical departments have hardly been responsible for any of the revolutionary advances in therapy in the last 40 years. The sort of clinical research which they teach may indeed be detrimental to the advancement of treatment and prevention of disease. In general they are concerned increasingly with the chronic and rare diseases for which treatment is not yet available, and the research physician becomes a physiologist with a passion for measurement. Given ever more sophisticated apparatus it is necessary to find something to measure, and research becomes more and more dictated by the tools available, with the result that time, energy, and money are too often squandered on "the trivial, the irrelevant, and the obvious."

The need for thought, observation, ideas, and hypotheses—the hard work of science—recedes, and the clinical scientist is relieved of the even harder task of practising medicine. Moreover, we are apt to forget that clinical research is applied research, and in carrying out experiments on human beings we should first pause to ask whether the research is likely to be wholly beneficial or actively detrimental. *Cui bono?* Do academic clinical departments absorb too many of our brightest young graduates who would be better employed in solving the pressing problems that confront humanity? Is the yield in ideas and results sufficient to justify

their existence, or do they merely provide, as Professor Martin Roth has put it, "occupational therapy for university staff"?

The pursuit of research has, of course, its own merit in creating an atmosphere of intellectual inquiry, and the able physician will be constantly stimulated by the problems posed by the individual patient. But his research must be relevant and it must be directed with the needs of the patient in mind. The beneficial collaboration between physician and surgeon in the accurate investigation and treatment of cardiac disease is a case in point, and advances in other fields are to be expected with the increasing partnership between doctors and technologists. But Platt's chief plea is to break the bonds imposed by measurement (which implies that man is merely a machine) and to repair what he believes to be the greatest failure of clinical science—the almost complete neglect of psychological factors in disease.

From earliest times man has built up elaborate defences against the analysis of his subconscious mind, and this is apparent in the medical schools of today. Patients are interrogated and examined in open outpatients and wards in the presence of numerous students, or are presented as "cases" at grand rounds. Clinical research is directed almost entirely towards organic disease, and until recently the mentally ill, together with psychiatrists, were conveniently segregated in separate institutions. And there are the additional defences that psychological medicine cannot be taught objectively and that the time is not ripe for serious

research. Yet no one denies the importance of such factors as heredity, emotional development, social, environmental and cultural influences, chemical changes, and organic cerebral disease in the causation of psychological illness. Each of these can be studied by modern techniques, and even the psychiatric interview is amenable to analysis by computer. Measurement and controlled experiment may not be possible, but "the unbiased collection and verification of observations"—the central feature of the scientific method—can still be satisfied. Human behaviour is surely a subject worthy of the clinical scientist.

Platt does not expect everyone to accept his views on the shortcomings of academic medicine nor his attempt at a solution. Nevertheless, he is really only reiterating what has been said before in other contexts—that in our effort to teach medicine as a scientific discipline we are in danger of losing those very qualities of understanding, compassion, and a carefully practised technique which are the essence of the good doctor. Science is in danger of becoming the master rather than a servant to be dismissed on the many occasions when the patient is better without its services. Man is presented to medical students today as a corpse or as a machine, and it is natural that their approach to illness should be largely mechanistic. A change in emphasis towards the scientific study of psychological factors in health and disease might well be the bridge to close the gap between the differing qualities of mind that often seem to separate the clinical scientist from the practising physician.

Clomiphene for Ovulation

The two articles on the artificial induction of ovulation in the *B.M.J.* this week come at a time when treatment with clomiphene citrate is passing from the research to the clinical stage. Preparations of human pituitary gonadotrophin are at present available for very few patients and under restricted circumstances. They are more dangerous than clomiphene, and their safe use necessitates elaborate facilities for hormone assay. Few would dispute that in the foreseeable future treatment with gonadotrophin preparations should be restricted to a few highly specialized units. Clomiphene, on the other hand, is available on prescription, and its untoward side-effects are slight.¹ Thus it is appropriate to consider the indications for prescribing the drug.

The first reports on treatment with clomiphene appeared nearly seven years ago,² and there is now general agreement on the indications for its use, its dosage, its side-effects, and the changes in ovarian hormone production which follow.³⁻⁵ The means by which its effects are brought about are not clear, so that some caution in prescribing it is wise. It is suitable only for the treatment of infertility associated with anovulation. In disorders of menstruation such as amenorrhoea it seldom brings any prolonged amelioration of the disorder.

In a woman having periods of amenorrhoea for more than three months it may be presumed that ovulation is sufficiently rare to be regarded as absent for clinical purposes. Among the questions that need to be determined before treatment for infertility is begun are whether she has a pituitary capable of producing gonadotrophins, ovaries capable of ovulating, and a uterus able to sustain a pregnancy. Clinical common

sense can do much to clarify the diagnosis before elaborate laboratory investigations need to be undertaken. A considerable proportion of patients with primary amenorrhoea have genetic defects such as Turner's syndrome or testicular feminization, or anatomical defects such as congenital absence of the uterus. None of them can be expected to respond to clomiphene. Primary amenorrhoea should therefore be investigated thoroughly before clomiphene therapy is undertaken. Secondary amenorrhoea poses more difficult questions. Some women have signs of low production of ovarian hormone, such as underdeveloped breasts, scanty pubic hair, and a flat vulva. Often this is due to deficient secretion of gonadotrophin by the pituitary. Treatment in this group is apt to be unsuccessful, as Dr. E. Rabau and colleagues show in their paper on page 446 this week. But enough of such women have a pituitary capable of response to make treatment worth trying, particularly if the results of laboratory tests are favourable. If the secondary sex characters are fully developed the outlook is more hopeful, particularly if ovarian enlargement can be detected or some virilization is evident.⁶

Infertility associated with secondary amenorrhoea can often be successfully treated with clomiphene. In carefully selected patients the success rate approaches 50%, but this can be achieved only after exacting preliminary laboratory investigation. Probably the most useful single test in selecting those amenorrhoeic patients who are suitable for clomiphene is an

assay of the urinary excretion of oestrone. Women who excrete more than 5 μ g. of oestrone per 24 hours have evidence of some residual ovarian activity and are likely to respond to the drug. A nonspecific method for assaying oestrogen, such as that successfully employed by Dr. D. Ferriman and his colleagues (page 444), gives some indication of ovarian response, but its sensitivity in distinguishing between those patients who are likely to respond to clomiphene and those who are not may be questioned. They found that patients with menstrual cycles of less than six months were more likely to respond successfully to clomiphene than those with longer cycles.

Women whose endogenous ovarian activity is sufficient for them to have fairly regular menstruation but who do not ovulate are the most rewarding group for clomiphene therapy, but they are also the most difficult to identify with any assurance. Endometrial biopsy and assay of urinary pregnanediol are more reliable means of detecting ovulation than basal temperature charts. Even for a nulliparous woman an endometrial biopsy should not entail more than a few hours in hospital and does not require an anaesthetic. The assay of urinary steroids like pregnanediol and oestrone is a different matter. These procedures have been out of the research stage for more than a decade, but few teaching hospitals have initiated specific techniques for carrying them out, most clinical centres lack facilities for doing them, and some use simplifications which are inadequate for clomiphene therapy.

There is little point in starting clomiphene therapy unless it can be established that the woman does not ovulate, is capable of ovulation, and has a fertile husband. To this end gonadotrophin assays are helpful, but they are available to few patients. Oestrogen and pregnanediol assays are well-nigh essential, and a semen analysis is mandatory. To determine whether a woman responded at all to clomiphene and when she ovulated requires nearly continuous 24-hour collections of urine for steroid assays over two to three weeks. This can be done on an outpatient basis; the diagnosis and therapy can be undertaken only with the aid of a specialist clinic. Without the collaboration of such services the use of clomiphene in general practice is clearly unwise. It is a fine example of a situation where the skilful use of laboratory resources can be of great benefit to a few people while a failure to use them can do harm to a larger number.

Blue Blood

In these days of egalitarianism blue blood is no longer the much sought after prerequisite of the nobility; indeed, it has of late become fashionable to disclaim such an inheritance. Nature unfortunately cannot be so denied; we are all the inheritors of blue blood, or almost all. Those of us who are not so endowed are certainly severely underprivileged members of the community, though it will take more than an Act of Parliament to put things right. Normal plasma contains a blue copper protein, caeruloplasmin, first isolated by C. G. Holmberg and C. B. Laurell^{1,2} in 1947 and 1948 and so named because of its colour. In 1952 I. H. Scheinberg and D. Gitlin³ showed that in patients with Wilson's disease this protein was markedly deficient or even entirely absent from the plasma, and they suggested that this was the primary metabolic defect in the disease.

The Scheinberg hypothesis was entirely reasonable; failure to elaborate this normal plasma protein resulted in the plasma copper remaining diffusible so that it entered the tissues in abnormal amounts. This led to basal ganglia degeneration in the brain and consequently to the bizarre sequence of motor disturbances which are so characteristic of the disease. In the liver excess copper led to necrosis and fibrosis, in the kidneys to defects of tubular reabsorption, and in the eyes to the typical Kayser-Fleischer pigment rings which are diagnostic of the disease. Unfortunately, as G. E. Cartwright and his associates⁴ have pointed out, in their experience—which mirrors that of most workers in this field—there is a poor correlation between caeruloplasmin concentration and the duration and severity of the clinical course of the illness. In fact, patients are occasionally seen with perfectly normal levels of this protein in their blood, as was early reported by A. G. Bearn and H. G. Kunkel⁵ and also by Cartwright's group.⁶

One possible explanation of this discrepancy, and a very attractive one at that, was the hypothesis that the caeruloplasmin present in some patients with Wilson's disease was structurally and therefore functionally abnormal. Thus there might be two different alleles mediating the disease, one leading to failure of protein synthesis and one to abnormalities of protein structure, either of which could give rise to the same disastrous functional derangement in the transport of copper in the body. This theory was discussed by a number of delegates at the London meeting on Wilson's disease held at the National Hospital in 1960,⁷ but we have had to wait for seven years before further light has been thrown on this aspect of the problem. Now N. A. Holtzman and his colleagues⁸ working at the Johns Hopkins Hospital in Baltimore have isolated and crystallized caeruloplasmin from a patient with Wilson's disease in whom the concentration of this protein in the blood approached normal levels. Their findings of a normal tryptic peptide map go a long way to disproving the theory of a structurally abnormal caeruloplasmin in Wilson's disease. These workers note, as others have done, that when treatment with penicillamine is instituted caeruloplasmin disappears from the plasma, and they postulate the occurrence of a reduced rate of synthesis of caeruloplasmin in their patient; when the excess copper stores were removed by penicillamine the stimulus to further synthesis of the protein became inadequate. This may well be true, but unfortunately it takes us no further in our understanding of the disease. Indeed, one of the main stumbling-blocks to our understanding of the pathogenesis of this mysterious illness is the complete absence of clues to the normal function of caeruloplasmin.⁹ L. Broman¹⁰ has even described it as "just an ineffective oxidase, in the wrong place, lacking a suitable substrate," but he himself believes that it represents a transport form of a copper-containing prosthetic

group which acts as an oxygen-activating unit in cytochrome oxidase. Unfortunately this theory too falls foul of the facts, which have an unpleasant habit of invalidating all the theories about this disease as fast as they are put forward. As S. B. Osborn and J. M. Walshe¹¹ pointed out earlier this year, it is possible for a patient with Wilson's disease, treated with pencillamine, to live a perfectly normal life with no symptoms of disease and with no detectable copper or caeruloplasmin in his serum—always provided that the drug is continued and the patient maintained in copper balance. So this would suggest an excretory function for caeruloplasmin. But this theory comes up against the work of the Albert Einstein group of workers,¹² who have shown, at least for rabbits, that the copper of catabolized caeruloplasmin "is not directly or preferentially excreted by hepatic, pancreatic, intestinal, or renal routes." Blue blood may be all very well in preventing Wilson's disease, but the way in which it mediates this function is as obscure as its role in ennobling the nobility.

Obstructive Airways Disease

The clinical features of the bronchial and emphysematous types of obstructive airways disease have been defined by A. C. Dornhorst¹ and T. Simpson² and their physiological characteristics by C. Ogilvie³ and by W. A. Briscoe and A. Cournand.⁴ The careful and detailed studies of C. M. Fletcher, B. Burrows, and others^{5, 6} firmly established the criteria whereby these two types can be distinguished. These workers have also tackled the semantic problem posed by the indiscriminate use of the terms "chronic bronchitis" and "emphysema," the first being favoured in Britain and the second in America. Using standardized clinical, radiographic, and physiological techniques, they compared 50 patients from a "bronchitis" clinic in London with 50 patients attending an "emphysema" clinic in Chicago.⁷ Apart from a rather greater incidence of disabling chest illness in London, there was no real difference in the pattern of obstructive airways disease for the two cities. In particular, the frequency of the bronchial and emphysematous forms was the same.

N. L. Jones, Burrows, and Fletcher⁸ have now extended this study by carrying out an annual review of the original 100 patients over a period of three years. During this time progress and mortality were remarkably similar in the two cities, but the incidence of disabling chest illness was higher among the London patients. However, a detailed questionnaire showed that bronchitic exacerbations were not in fact more frequent in London than in Chicago but only more disabling in terms of the time spent in bed or off work. The authors attribute this to differences in working conditions, sickness benefits, and cost of treatment between the two cities rather than to differences in the behaviour of the disease process itself.

This recent survey also gives valuable information on the

relative prognosis of the two types of obstructive airways disease. The mortality was higher in the bronchial (36%) than in the emphysematous group (15%), and this was related to the greater incidence of hypercapnia among the bronchitic patients. It might have been thought that the complications of bronchitis (infection, hypercapnia, and right heart failure) would prove more amenable to treatment than the irreversible lung changes of emphysema. The actual finding of a much higher death rate for bronchitis surely points to the need for a reappraisal of therapeutic methods used in this formidable disease. The thorough techniques of investigation evolved by Fletcher and his co-workers could well provide the basis for a study of this kind.

Realism and Addicts

The Ministry of Health is facing increasing criticism because of its alleged dilatoriness in responding effectively to the threat of epidemic heroin addiction in Britain. A brief inquiry published by the *Guardian*¹ last week certainly gives a picture more of disarray than preparedness so far as hospital services are concerned, while a speaker at a recent meeting of the General Medical Services Committee² denounced "a typical Ministry paper scheme," which he alleged was simply putting forward proposals which could not be implemented owing to lack of facilities. To what extent are such strictures justified?

The latest "paper scheme" is a memorandum dealing with the rehabilitation and aftercare of heroin addicts.³ The G.M.S. Committee has already drawn attention to the inappropriateness of the use of the allocation procedure to place an addict on a general practitioner's list, but otherwise the ideas put forward in this memorandum deserve nothing but praise. It presents a humane and intelligent approach to the problem of drug addiction, stressing that detoxification by itself is not enough, and picturing narcotic addiction as requiring comprehensive integrated services—clinics, hospitals, hostels, work-training—rather than mere drug-handout centres. The memorandum supplements the model for hospital treatment which was put forward earlier this year.⁴

The trouble comes when turning from the Ministry's memoranda to the realities. Those in Alexander Fleming House seem to have some of the characteristics of the kind of student who writes alpha papers but muffs the practicals. To take an example: one of the most important proposals in the new circular concerns the role of hostels in the aftercare of addicts, and the benefits that can result from grouping patients are discussed with a degree of sympathy and insight which is admirable: "Although the establishment of a disciplined atmosphere is essential this alone is insufficient to prevent drug taking. It is necessary to build up an atmosphere of co-operation between staff and residents and in this task the psychiatrist can give valuable assistance. . . . The expectation of the hostel must not be set too high and staff must accept the probability that relapse will take place and be ready to contend with its effects on other residents and themselves." A splendid answer in a written paper, but then take the example further and look at the performance in the practicals.

How many hostels for addicts of the sort which the Ministry envisages are now functioning in London? Not one. Who is going to pay for these no doubt very expensive facilities? The Ministry makes hopeful murmurs about local health authorities footing the bill, but anyone with experience of that method of financing will know that ratepayers are always eager for new ventures to be sited in any borough but their own. Where are the staff of the hostels to be found? These and every other question which bears on reality meet with no answer.

The earlier suggestions on hospital care were of course similarly worthy and invited a volley of equally unanswered questions. Where are the consultant sessions to be found for the new treatment centres? Are new psychiatrists to be manufactured, or will they be withdrawn from other services? What training courses have been arranged? What laboratory facilities are being provided? Will extra psychiatric social workers be hired? How much money will be spent?⁵

It would not be fair to place all the blame on the Ministry for failing to find an immediate solution to this extremely difficult problem. To a large extent the solution (and responsibility) lies in the hands of local health authorities and hospitals, general practitioners and voluntary bodies: imagination, energy, and good organization are needed in the many local communities where drug addiction is established or beginning to be seen. All the blame may not be the Ministry's, but it is reasonable to ask for more practical action and more evidence of a sense of urgency. In 1954 there were 57 known narcotic addicts, while in contrast the present official count is 1,349.⁶ With a situation as threatening as this today's minor blunders, procrastinations, or meanness are the stuff out of which tomorrow's disasters are likely to be made.

Surfer's Nodules

All that some people ask is not a tall ship and a star to steer her by but a board that measures ten feet by two, has a core of polyethylene foam with springers of spruce or redwood, is jacketed in fibreglass and resin, and coated in paraffin wax to provide adhesion for its rider. J. G. Erickson and G. R. von Gemmingen¹ have described some of the hazards of surfboarding as it is practised in Southern California. It sounds much less comfortable than riding on a dolphin's back. The devotee "paddles in the kneeling position with his feet extending back and his body weight balanced on the tibial prominences, the middle of the top of the feet, and the dorsum of one or more metatarso-phalangeal joints . . . over months of surfing, at four to six hours a day." In this attitude he travels seaward in search of the perfect wave upon whose back he can ride shoreward in triumph and delight.

In these days of increased leisure it is becoming harder to draw any sharp distinction between work and sport as an occupation on the one hand and as a relaxation on the other. Indeed, some people would say that the point has been reached at which work has become a relaxation from the obsessive pursuit of a hobby. The surfers of Southern California seem a case in point. They pay for their devotion with nodules, ulcers, ganglia, and bony changes—attributable mainly to the effects of long-continued pressure—and, more hazardously, by taking the chance of being run down by their colleagues in the open sea. Though the pressure effects are avoidable

by temporary abstinence or by spreading the load, there is little enthusiasm for avoiding what is acknowledged to be a badge of distinction, since "the prestige of the surfer is proportional to the size of his nodule." "Abstinence," said Blake, if his shade will forgive this use of his words, "sows sand all over the ruddy limbs and flaming hair, but desire gratified plants fruits of life and beauty there." It seems unlikely that modern Britons will try to rule the waves so obsessively, if only because Pacific rollers offer better sport, but even so we could perhaps find examples of surfer's nodules upon our own shores, and students of occupational marks would no doubt like to add this new piece to their collections.

Platelets in Uraemia

The tendency of patients with advanced uraemia to bleed is associated with a defect in their platelets.¹⁻³ The more severe this abnormality in the platelets, the more marked are the clinical manifestations of bleeding.^{4,5} Thrombocytopenia may also occur, particularly in patients with acute renal failure, but the platelet count is normal in most patients with chronic uraemia. The impaired function of the platelets is manifested by an increase in the bleeding time, defective platelet adhesiveness, reduced platelet aggregation in the presence of adenosine diphosphate, impaired clot retraction, reduced prothrombin consumption, and poor availability of platelet factor 3. The earlier report of A. J. Hellem and his colleagues⁶ that intravenous infusion of urea prolonged the bleeding time and reduced platelet adhesiveness has not been confirmed by P. A. Castaldi, M. C. Rozenberg, and J. H. Stewart.^{7,8} Substances other than urea are now presumed to cause the functional platelet defect in uraemia.

Recently, Stewart and Castaldi⁷ have reported that platelet function in uraemia was considerably improved by dialysis (either peritoneal or haemodialysis), though complete correction—particularly of the bleeding time and platelet aggregation—was not achieved. The clinical improvement in haemostasis paralleled that in platelet function. Dialysis usually improved clot retraction, prothrombin consumption, and platelet adhesiveness. In most patients there was a rise in the platelet count after dialysis. Improvement in platelet function was found as early as one day after dialysis, and occurred in two cases with little fall in the level of urea in the blood. Successful renal transplantation was more effective than dialysis in restoring completely normal haemostasis.

Stewart and Castaldi used measurements of platelet aggregation, availability of factor 3, and clot retraction to estimate platelet function in vitro. No adverse effects were observed after the addition to plasma rich in platelets of urea, dextrose, mannitol, creatinine, urate, phosphate, potassium, or magnesium; or after changes of pH or osmolarity within the range which might be found in severely uraemic patients.

¹ Erickson, J. G., and von Gemmingen, G. R., *J. Amer. med. Ass.*, 1967, **201**, 134.

The abnormality in the platelets in plasma rich in platelets taken from uraemic patients could not be corrected in vitro by dialysis or by adding normal plasma poor in platelets. However, the failure of dialysis in vitro does not exclude a direct effect; restoration of function may not occur until the platelets have been returned to the circulation or have been in a normal environment for a longer time than the period of the in vitro test.

From their observations Stewart and Castaldi conclude that the qualitative platelet defect in uraemic patients is caused by the retention of a dialysable substance which would normally be excreted by the kidney. The impairment of function may be due to the net effect of many substances, but it is possible that a single agent is solely or largely responsible. More recently H. L. Horowitz and his colleagues⁸ have reported a defect in the activation of platelet factor 3 by adenosine diphosphate in blood from uraemic patients. Further studies pointed to the presence of an inhibitor of this reaction in the plasma of these patients, and preliminary observations suggest that the inhibitory factor may be a newly described intermediate of urea metabolism, guanidosuccinic acid. If this can be confirmed we may look forward to further advances in the knowledge of the physiology and pathology of platelets.

Chicken-pox Pneumonia

Chicken-pox is generally a trivial infection in children, but it tends to be more severe in adults and may be accompanied by pneumonia caused directly by the virus. Various surveys¹⁻³ in the U.S.A. have placed the incidence of chicken-pox pneumonia in adults between 16 and 33%, but it is found less frequently in Britain. The disease varies greatly in severity.⁴ At one extreme it can be a catastrophic illness characterized by severe dyspnoea, cyanosis, haemoptysis, and prostration, at the other a condition so mild that it can be detected only by routine radiography.

In a typical attack the patient is an adult with a heavy rash, which has usually been present for two to five days, in whom the spread of the disease to the lungs is heralded by a dry cough followed by increasing breathlessness and cyanosis. Abnormal signs are seldom present initially, but as the patient's condition deteriorates air entry diminishes and adventitious sounds are heard. The classical signs of consolidation are not found. After 48 hours the cough becomes productive of scanty mucoid sputum, which may be streaked with blood. Occasionally there is a more severe haemoptysis. Culture of sputum gives a sparse growth of bacteria, mainly commensals. The white blood cell count is usually normal but may show a polymorphonuclear leucocytosis. The sedimentation rate is rarely raised. After a week the patient's condition begins to improve and towards the end of the second week he emerges from the critical phase to face a prolonged period of convalescence. The cough and abnormal chest signs quickly disappear, but breathlessness may persist for

several weeks. If the illness is associated with neoplastic disease or pregnancy the prognosis is poor.

During the acute phase x-ray examination shows widespread nodular opacities in both lung fields. The lesions vary in size from several millimetres to more than one centimetre. In most patients resolution occurs within eight weeks,⁵ but occasionally a coarse reticular pattern of small, very soft nodules persists for years.⁶ J. B. Mackay and P. Cairney⁷ first drew attention to the association between chicken-pox in adult life and miliary calcification of the lungs. Their observations have been confirmed by A. F. Knyvett,⁸ who followed three patients from the early stage of soft nodular shadowing to calcification.

Chicken-pox pneumonia should be suspected if respiratory symptoms develop during the acute eruptive stage. When mild no special treatment is required, but patients with respiratory distress need skilled nursing in hospital. Though antibiotics have no obvious effect, they are usually prescribed for seriously ill patients in the hope of controlling secondary bacterial infection. The value of corticosteroid drugs is controversial. Rapid improvement may sometimes follow their administration, but on other occasions they fail to avert disaster. However, they do not appear to be harmful when given for the first time during the acute stage of chicken-pox. Beneficial results have been reported from the use of hyperimmune gammaglobulin,⁹ but further experience is required before its value in severe chicken-pox can be assessed, and supplies are extremely limited. Oxygen should always be given to patients with chicken-pox pneumonia who show deep cyanosis; should this persist tracheostomy and intermittent positive pressure respiration may prove life-saving.⁹

The Royal Society

The new premises of the Royal Society at 6 to 9 Carlton House Terrace were formally opened by the Queen on Tuesday this week. It was the first time that the Monarch, as Patron, had personally opened a new home of the Society. Her Majesty was accompanied by Prince Philip, Duke of Edinburgh, and Earl Mountbatten of Burma, both Fellows of the Society.

In the three centuries of its existence the Royal Society has occupied homes in Gresham College in the City of London, in Crane Court in Fleet Street, in Somerset House, and for the past century in Burlington House, Piccadilly. At Burlington House the Society's activities greatly increased in response to the growing importance of science in the community. The office staff of two in 1873 is now nearly 80, and not all of them could be accommodated in the building.

The new premises provide more than twice the space the Society had before. They have been formed by adapting four separate houses, the work of conversion being financed by an appeal fund launched by Lord Florey when he was president. Their situation, finely illustrated in a commemorative booklet, is unusually attractive. Not only do they face St. James's Park and the Mall but they are on the main pedestrian route between Parliament Square and the centre of the West End.

In congratulating the Society as it embarks on another stage of its development, we are sure that its new headquarters in the heart of the metropolis, made possible by the efforts of many people over a period of years, will be a source of pride and inspiration to the Society as it continues to play an increasingly significant part in the world of science.

Harvey and the Scientific Method†

If any testimony were needed to the unique position of William Harvey in the development of modern medicine, it would be sufficient to note that after more than three centuries new researches into his life and work continue to be made and have yielded in the last few years a quite astonishing harvest. Notable among them are the recent volume by Keynes (1966), so rich in learning yet so delightful to read, and that unique triumph of erudition and insight, the new transcription of Harvey's *Prælectiones* by Gweneth Whitteridge (1964, 1966), together with her interpretation of the manner and sequence in which they were written, so that we are now almost able to follow the trains of thought which led to the gradual revelation of the secrets of the circulation of the blood, in Harvey's mind.

As to his methods, there is no better source than *De Motu Cordis et Sanguinis* itself, and perhaps Harvey's own writings in reply to Riolan. Harvey described his work as proving the circulation of the blood "by reason and experiment." It is indeed the charm of *De Motu* to the present-day scientist that reason and experiment go hand in hand throughout, the experiment being carefully devised to prove or refute the hypothesis, the hypothesis having been derived from experience and the contemplation of data carefully observed, the perfect scientific method, in fact.

In spite of this, Harvey knew that in his day his methods and his conclusions were so unorthodox that they would be criticized and rejected by many of his contemporaries, and he said: "I fear lest I have mankind at large for my enemies, so much doth wont and custom become a second nature. Doctrine once sown strikes deep its root, and respect for antiquity influences all men. Still the die is cast and my trust is in the love of truth and the candour of cultivated minds."¹

Harvey's contemporaries and successors, nevertheless, generally accepted his teaching, but failed to find any way of making it relevant to medical practice. This was inevitable at that time, but they might have been quicker to adopt his experimental methods in the pursuit of the further knowledge of physiology.

As to his practice of medicine, Harvey was considerably criticized during his lifetime, and it is interesting that Lord Conway warned his daughter, who was a patient of Harvey's, against him, in spite of his obvious esteem for Harvey's scientific merit.

John Aubrey said of Harvey: "All his profession would allow him to be an excellent Anatomist, but I never heard of any that admired his therapeutic way. I knew several

practisers in this Towne London that would not have given 3d. for one of his Bills and that a man could hardly tell by one of his Bills what he did aime at." Dr. Broun, a generation after Harvey, said that his discovery had "seemed to illustrate the theorie of Medicine, yet it made no improvement in the practice thereof" (Clark, 1964). Sydenham, in his various writings on clinical subjects, did not mention Harvey's work at all.

But before we pursue the results of Harvey's experimental work, let us end with John Aubrey's comment on his character. He tells how Harvey made him "sitt by him two or three hours together in his meditating apartment discoursing.

"He was very far from bigotry. Why, had he been stiffe, starcht and retired, as other formall Doctors are, he had known no more than they. From the meanest, in some way or other, the learnedst man may learn something. Pride has been one of the greatest stoppers of the Advancement of Learning."

Aubrey clearly recognized Harvey as a great man.

Fruits of Science

There was, in fact, a period of more than 200 years before experimental physiology on Harveian lines can be said to have begun. Müller, Helmholtz, and, above all, Claude Bernard on the Continent, William Sharpey and Marshall Hall in England, and later Starling, Bayliss, and J. S. Haldane are names which come to mind, but the introduction of the methods of experimental physiology to clinical medicine is something which really belongs to my own time. Its development has been rapid and productive, so that today, all over the world, universities have their academic clinical departments, staffed for the most part with the descendants of Harvey, Bernard, and Starling, rather than the descendants of Sydenham and Osler, and engaged almost entirely in the application of the Harveian method to the investigation of bodily function and the manifestations of disease, in the course of which they have, as Harvey predicted, gained much from the study of nature's own experiments.

This has led to a new understanding of the scientific basis of medicine, comparable in its significance with Harvey's discovery of the circulation. The physiology and functional pathology of disorders of metabolism, of the heart, lungs, and kidneys, and of the digestive system, have all proved to be rich sources of study by these methods, and in some areas the physician has virtually taken over the role of physiologist.

Large and increasing funds from public and private sources have been devoted to medical research of this kind, and more and more persons have been attracted into careers in clinical science. The impact of science and technology has brought new skills and refinements into diagnostic methods.

On the therapeutic and preventive side of medicine we have, in my time, seen the virtual conquest of bacterial disease,

* Harveian Oration delivered to the Royal College of Physicians of London on 18 October 1967.

† This introductory section is somewhat abbreviated from the spoken version, which contained more material concerning Harvey's relation with the College of Physicians.

¹ The wording is my modification of Richard Asher's modification of Bowie's revision of Willis's *Transcription* and is near enough to a translation of Harvey's Latin in chapter VIII of *De Motu*.

including tuberculosis, and the prevention of poliomyelitis. Fatal diseases such as pernicious anaemia and severe diabetes are now controlled; cancer of the lung is known to be largely preventable. Modern anaesthesia and antibiotics, along with new technical cunning, have combined to make cardiac surgery a reality. Except in the most primitive parts of the world, plague is a thing of the past, and if malaria is not already eradicated it is for want of resources and not for want of knowledge. The overpopulation resulting from the conquest of disease could now be countered by modern means of contraception, which with little doubt will soon be further improved.

To this audience there is no need, and no time, for a full catalogue of the victories. One has only to think back to quite recent history, the plagues of the seventeenth century, the infant mortality of the eighteenth and nineteenth centuries, the deaths of Chopin and Keats and the Brontës from tuberculosis, to be grateful for the achievements of scientific medicine.

Critical Survey

The adoption of the scientific method in the Harveian tradition by clinical medicine has been recognized by the appointment of about 43 wholtime professors of medicine or of therapeutics in the United Kingdom alone.² The growth of departments of academic medicine in the United States has taken place at the same time on an even larger scale. Their contributions to the understanding of disease are established, real, and secure, and they have helped to make possible the deployment of the discoveries of modern medical science, both in relation to treatment and in diagnosis. Yet we must face the fact that these departments have not been responsible for, nor even seriously involved in, any of the discoveries in therapeutics or preventive medicine which I have just enumerated.

The antibacterial action of the sulphonamides was wholly worked out in the laboratories of pharmaceutical industry, starting with Mietsch and Klarer and taken up by Domagk, though the original idea that dyes could be antibacterial stems from Ehrlich. From the sulphonamides, hypoglycaemic agents such as tolbutamide have developed, and a whole series of diuretics of the chlorothiazide class.

The antibiotics originally sprang from an observation of Pasteur and Joubert of 1867, but Fleming's findings of 1929, which he left undeveloped for 10 years, were then taken up by Florey and Chain, who isolated penicillin and demonstrated its effectiveness. Attempts at synthesis were an expensive failure, but better culture methods developed in American Governmental laboratories and by the Pfizer drug company made penicillin a practical success. From the penicillin idea comes streptomycin, discovered by Waksman and his colleagues in a university department, and developed by Merck. All the subsequent antibiotics have originated in industrial laboratories. None has depended on clinical scientific departments or on the kind of clinical science which they teach.

Isoniazid and para-aminosalicylic acid have arisen from the combined work of academic and industrial departments. The new penicillins have come from the Beecham Laboratories.

Poliomyelitis vaccines have been developed by non-clinical scientists.

Liver treatment of pernicious anaemia was an exception, coming as it did from Minot and Murphy in an academic medical unit, taking a rather long shot from animal work by Robschert-Robbins and Whipple, which could have been quite irrelevant. These latter workers had suggested that there might be some "parent pigment substances" normally stored

in the liver. In spite of this lucky and favourable beginning the hard scientific work of isolating vitamin B₁₂, the active principle, was accomplished by scientists in the pharmaceutical industry in Britain and the United States.

Insulin, as everyone knows, was first extracted in a physiology department, and almost stands alone as having resulted from good scientific reasoning. The discovery that carcinoma of the lung was caused by cigarette smoking was due to clinical observation, followed by a first-class study by the techniques of epidemiology.

The synthesis of cortisone was combined work between an academic non-clinical scientist and a drug firm—namely, Merck—done as part of a wartime programme sponsored by the United States Office of Scientific Research and Development. But Hench, of the Mayo Clinic, made a clinical contribution to the cortisone story which was of great importance, especially as he had to some extent predicted the results by clinical observation. Stilboestrol came from an academic non-clinical laboratory.

To continue the recital would be tedious, but the findings are essentially the same when we look into the origins of anaesthetics, tranquilizers, vitamins, antimalarials, antihistamines, hypotensives, sex hormones, and oral contraceptives. Not one originated in a department of academic medicine or therapeutics. Even D.D.T., so important to preventive medicine, was discovered by Müller, working for the Geigy company.

I must acknowledge here my debt to Dr. William Bain for helping to ensure that my information is accurate and for calling my attention to Professor Ernst Chain's Trueman Wood Lecture of 1963, which contains most of the relevant information.

Ideas and Resources

If we are to draw any tentative conclusions from this survey of the origins of the control of human disease in our time, we might wonder whether the establishment of scientific clinical units interested in the exact study and measurement of the phenomena of disease has, like Harvey, succeeded in illuminating "the Theorie rather than the practice of Medicine," for the phenomenal success of modern medical treatment seems to have depended almost wholly on non-clinical, often non-medical, scientists, frequently working in, or in close collaboration with, the pharmaceutical industry. And it would be a serious mistake to think that the role of industry has been largely in the field of commercial development. A great deal of the basic scientific work, especially chemical isolation, analysis, and synthesis, has taken place there.

Ideas come from lucky accidents or from the inspiration of men of imagination. At the next stage, where the idea needs to be worked out, there seems to be a strong case for directing resources deliberately to the achievement of an objective, rather than devoting so much of our research potential to the investigation of observed phenomena of academic interest. In fact, both the Ministry of Health and the Medical Research Council have in recent years called together conferences and working parties with the object of seeing how money and manpower may best be applied to the achievement of specific objectives; for instance, in intensive coronary care, recurrent dialysis, leukaemia, and pyelonephritis. This may need resources not always to be found in academic and Research Council laboratories, and might require a major redeployment of Research Council funds. Where ideas have originated in the academic laboratory, collaboration with industry, not necessarily only the pharmaceutical industry, if required, should be sought early and willingly, not reluctantly and belatedly.

Some real discoveries have been made in academic clinical departments, often in the field of rare disease, such as primary aldosteronism, but the accurate study of function in chronic destructive disease of the lungs, the kidneys, and the liver has

² This includes the occupants of personal chairs in medicine and related subjects, such as neurology and cardiology, but does not include psychiatry, paediatrics, or preventive medicine, nor surgery, nor gynaecology, nor laboratory medicine, such as pathology.

sometimes seemed more akin to an absorbing hobby than a therapeutic exercise, though occasional and temporary relief to the patient may be a by-product.

It was predictable that the prevention of silicosis would not derive from refined studies of pulmonary function, and that lasting benefit in chronic renal failure could only come from something which would replace the kidneys—that is, transplantation—or take over their function—that is, repeated dialysis. These methods are now being developed and basic scientific work on the consequences of renal failure has been an important preliminary to their proper use.

Methods of resuscitation occasionally save lives worth saving, as in the treatment of cardiac arrest, but are all too often employed in keeping alive those who would by any possible standard be better dead.

Perhaps the most important therapeutic gains in which clinical scientific departments have played a part have been in the electrolyte field and in endocrinology (though few of these latter have been initiated there), and in cases where physician and surgeon collaborate in the accurate investigation and subsequent surgical treatment of defined conditions, as in cardiac surgery.

Perhaps it does not matter that the academic clinical departments of medicine and therapeutics have not contributed as much as one might have hoped to the treatment and prevention of disease. So much has been done by the non-clinical scientists, together with the drug firms, that the clinical departments have been left with the hard core of chronic disease in an ageing population, which is rather barren soil to cultivate.

A Paradox

But here we come across what Rustein (1967) has called the paradox of modern medicine. The expectation of life in the United States has remained almost stationary for the last 15 years or so and has in fact fallen well below that of other countries, such as Sweden and the United Kingdom. Yet this is not just a phenomenon of the aged, for in males of 15 to 44 years, for instance, the death rate is notably higher in the United States than in Sweden for every major cause of death except suicide. At the same time the infant mortality has failed to improve as compared with other countries, and all this is despite the fact that federal expenditure on biomedical research in universities and hospitals³ in the United States has increased during the last 20 years from \$1m. to \$1,000m.

To return to the clinical scientific departments, I have already acknowledged their contributions to the application of scientific discovery at the bedside. The very pursuit of research, moreover, provided that it is relevant, has merit in its own right in creating an atmosphere of intelligent inquiry; but in medicine the practising physician who is intensely interested in the diagnosis and treatment of the individual patient and responds to the challenge which every fresh patient brings has his own constant stimulus to intellectual inquiry and need not be ashamed if he finds the added burden of organized scientific research something of a distraction. A great deal of modern practice in medicine and surgery has been evolved by men whose researches were part of their daily clinical tasks. Cardiology and neurosurgery are good examples.

The situation in clinical research is bound to be different from that in the laboratory sciences which contribute to medicine. All clinical research is, and must be, applied research. To ask a protein chemist what use his work is going to be to mankind would be an impertinence, but we are entitled to ask *Cui bono?* of a clinical scientist carrying out investigations on patients. And we have a duty to pause from time to time and ask whether clinical science is wholly beneficial, or whether there could even be instances in which its influence was

actually detrimental. For instance, has the obsession for measuring what are now called *parameters* in chronic organic illness led to the neglect of other and more important problems? Do the scientific clinical departments absorb almost all the research potential of our best graduates and thereby deplete the pool available for research directed towards current problems of really pressing nature, such as drug addiction, neurosis, oral contraception, delinquency, alcoholism, aggression, and the prevention of lung cancer?

Is the Harveian method, as interpreted by clinical science, ever really likely to yield therapeutic results? Has it already reached a point of diminishing returns? Does medical science, as taught in academic clinical departments, really develop the prepared mind? If so, why have not more of the ideas behind modern therapy sprung from these departments? Finally, is medical education too much dominated by the clinical scientists at the present time? Some of these questions it will be my endeavour to examine.

Further Heresy

The demands of the clinical scientists for ever more expensive and sophisticated apparatus are justifiable if the things to be measured by the apparatus are relevant and important to the study of human health and disease, and if they cannot be equally well assessed by simpler methods, but no one who has been involved in the disbursement of funds for clinical research can come away without misgivings about whether time, talent, and money are sometimes squandered on the measurement of the trivial, the irrelevant, and the obvious. Given a new and expensive tool such as a gas chromatograph, an electromagnetic flowmeter, or a multichannel recorder of some kind, it becomes all too easy to find a subject for research; for there is bound to be something which has not yet been measured by these means. The need for thought, observation, ideas, and hypothesis, which form the hard work of research, recedes comfortably into the background for a year or two, while the research worker, supported by a grant and relieved of the much harder task of practising medicine, collects his results and has them analysed for him by a computer. One has the impression at times that the thought process starts with "What experiments can be done with these tools?" and that the "imaginative episode of thought" so essential to good scientific discovery has been bypassed. Medawar on scientific method should be required reading in all clinical scientific departments. And Harvey's *De Motu Cordis*.

It is only a very slight exaggeration of the truth to say that I have seen applications for an electroencephalograph to tell whether the subjects of the experiment are awake or asleep, and for a recording device to tell whether a baby is crying; and that I have recently listened to an account of scientific work which seemed to demonstrate beyond reasonable doubt that getting hot is closely correlated with sweating. No wonder that a friend of mine who has a gift for felicitous expression has distinguished between "ideas" research on the one hand and "occupational therapy for the university staff" on the other, and once referred to a research project as "squeezing the last drop of blood out of a foregone conclusion." I am afraid I am not one of those who would count it a triumph of modern medical science that it is possible to measure the blood-flow through the liver in a patient with mitral stenosis who is being exercised on a bicycle ergometer. There is no special significance in this particular example, which is only one of many that could be chosen. At its best this kind of experiment makes a trivial addition to human knowledge, at its worst another contribution to the already bulging archives of the Pappworth (1967) collection.

Research is supposed to train the mind into channels of scientific (and therefore respectable) thought, but does not this kind of research sometimes encourage the erroneous belief that

³ Distributed through the National Institutes of Health.

only that which can be measured is worthy of serious attention? "Not everything we count counts. Not everything that counts can be counted," was wisely said by Dr. Stephen Ross (Jason, 1966). And what kind of impact does the human guinea-pig make on medical students?

But if we are seriously and in all sincerity to try to assess the debit side of clinical science, then unhesitatingly I would put among its greatest failures its almost complete neglect of psychological factors in disease, and this is my next theme.

The Mind

The proper study of mankind is of eternal and absorbing interest, not because man is a chemical engine, as one scientist has told me, for that is an attribute which man shares with the amoeba, but because of the endless variety of the interplay of human personality, intellect, emotion, and motivation. That is what all great literature and great poetry have been about; it is the raw material of nearly every interesting conversation, whether in the senior common room or on the Clapham omnibus.

Yet what is acceptable to read in literature is not always acceptable if it threatens to become an analysis of our own unconscious mind, and man has from earliest times built up an elaborate series of defences lest his carefully sublimated emotions and motivations come disturbingly into consciousness. The defences have taken various forms: the material walls of monasteries, nunneries, and colleges, for instance, where the intelligentsia could isolate themselves from the undesirable and disturbing contacts of everyday life. Sir Arthur Thomson, in his Harveian Oration of 1961, recounted how that wealthy scientist, Henry Cavendish, once met a housemaid on the stairs of one of his mansions and promptly had another staircase built so that this encounter could not recur.

Taboos have been built up and rationalizations and fantasies, of which the legend of the Garden of Eden is surely one of the supreme and most ingenuous of examples.

Freud tried to bring us up against stark reality, but, in spite of him, these defences are as clear in a medical school today as in any other seat of learning.

Walls have been built to segregate those who are mentally ill, but they had the great advantage of isolating not only the patients but also the psychiatrists, who, until the second world war, were almost never allowed in a teaching hospital.

Sex education was taboo until quite recently, and still is in many—perhaps most—medical schools, unless one includes under that term the anatomy of corpses, the study of venereal disease, and the chemistry of hormones. Not my idea of an acceptable introduction to the biology, psychology, sociology, and aesthetics of sex.

"Clinical Material"

Patients, often hideously called the "clinical material" of teaching and research, have been drawn so far as possible from the lower social classes (everyone well brought up knows that the lower social classes have no emotional needs or feelings), and were, and still are, interrogated either in an almost open outpatient department in the presence of numerous students or recumbent in a hospital bed in an open ward; conditions chosen with unerring insight to ensure that the psychological factors in disease, even if present, cannot obtrude and disturb the proper pursuit of scientific medicine. But to make assurance doubly sure, the ward round is conducted as a ritual, the chief followed by his numerous attendants.

The advent of the professorial medical departments, which should have brought with it new attitudes towards patients consistent with the new understanding of interpersonal relations, has in some instances merely reinforced the defences by

a more refined and narrow choice of the "clinical material," by the abhorrence of private practice (thus ensuring that the patient cannot call the tune), and by the development of grand rounds to replace the ritual visits of former years. I have seen a patient wheeled in and demonstrated to a large meeting and wheeled out again without a single word being said to her—not even a word of thanks. Finally, the study of anything except organic disease is dismissed as unscientific. I have heard a research worker who has studied rheumatic disease for many years confess without apparent shame or embarrassment that the idea of investigating psychological factors had never been seriously considered.

Psychological Factors

The advent of the psychiatrists, so long as they can continue to be classed as eccentrics and therefore isolated from the main stream of clinical teaching and research, allows for the continued segregation of personality and emotional problems.

If challenged with neglect of psychological factors in disease, the usual defence mechanism of the clinical scientist is strangely and illogically three-phased: "In psychological medicine there is no corpus of proved knowledge to teach; if there is, there is no way of teaching it; in any case, I teach and practise it myself." Believe me, I am not describing something out of my distant student days, but recounting, without exaggeration, facts and opinions which have come to me through personal contacts during the last two years.

And yet the extent to which the mind and personality influence all illness must be obvious to any who do not close their eyes to the realities around them. One has only to observe two diabetics, for instance, scientifically indistinguishable, both requiring diet and insulin, to see how one will retreat into neurotic invalidism, abetted by his wife in the building of an elaborate and protective ritual, while the other regards his daily life as almost uninfluenced by a few minor inconveniences.

Of course clinical teachers vary greatly in their approach to these problems, and psychiatrists vary too in the amount of help and collaboration they are prepared or, let us admit, equipped to give; but even those who, like myself, have always delighted in the study of people do not, I think, sufficiently realize the amount of our neglect and the full extent of our conformity—"so much doth wont and custom become a second nature"—for we have not asked ourselves the essentially Darwinian-cum-Freudian question—to what end and for what purpose and in response to what selective pressures have the teaching hospitals evolved in this way?

From a research point of view, the defence which requires most serious thought is that "the time is not yet ripe for serious research into psychological medicine. Like infective disease before Pasteur, it awaits a break-through in knowledge." This view, which is rather a favourite at the present time, seems to me quite untenable today. The nature of infectious disease before Pasteur was quite unknown. Though the causes of psychological illness are multiple, varied, and infinitely complex, no one doubts that they are to be found in interactions between heredity, emotional development, social, environmental, and cultural influences, chemical changes (including drug action), and organic cerebral disease. Every one of these can be studied today by methods far more rigorous than existed even a few years ago. Indeed, they are being studied already to great advantage.

New Approaches

Important in this is the study of symptoms revealed by the psychiatric interview aided by modern knowledge of observer error and computer techniques of information storage and analysis, and the validation of methods and conclusions. There

is room for new approaches to the study of human behaviour in health and disease, on the lines of Tinbergen, Lorenz, and Desmond Morris.

"The central features of scientific method," says Martin Roth (1967), "are the dispassionate observation, recording and analysis of data aimed at deriving reliable answers to clearly formulated theoretical and practical questions. The advantages of quantification and controlled experiment are undeniable. But they may be inappropriate or applicable only to a limited extent at certain stages in the development of systematic inquiries in some fields of knowledge. This need not disqualify a discipline from scientific status, provided that the essential criterion, the unbiased collection and verification of observations can be satisfied."

Or, as Gaylord Simpson (1963) has said, the multiplication of relevant observations will not prove a hypothesis, but the more that they fail to disprove it the more confidence we have in the hypothesis; but the proviso is that the observations must be relevant, and to be relevant they must be capable of disproving the hypothesis. These surely were the methods of Darwin, of which we have no need to be ashamed.

There is enough in psychological medicine to keep an army of research workers fully employed for many years, but we shall not attract enough of the right men and women into the study of the mind if we continue to give medical students in their early and formative years no contact with man except as a corpse or a machine, and continue to build up elaborate defences between ourselves and the minds of our patients.

Should anyone doubt whether human behaviour is a fit subject for study, let him make observations on his colleagues, especially in committee. He will soon find behaviour patterns as specific as the song of the thrush; and let him inject noxious stimuli in the form of unwelcome concepts from time to time, and he will find that defence mechanisms springing direct from the unconscious, uninhibited by the rules of logic, surface promptly to the appropriate summons. But perhaps I have been overzealous in what probably amounts, for me, to replacement therapy in my period of bereavement for the loss of clinical medicine, my constant companion for about 45 years, and I had better turn rather hastily to my last subject.

Medicine versus Science

The real distinction between medicine and science is not, of course, a matter of method, nor is it the recognition that man is something more than a machine. It is a matter of aims. The object of the true scientist is discovery; the object of the doctor is to plan the method of action judged to be of best value to the individual. That the aims are different is undeniable; fortunately they do not have to be invariably in conflict.

The first need of the doctor is to have knowledge of the human body and mind in health and disease. Clinical science in medical departments has contributed greatly to knowledge of the body and almost not at all to knowledge of the mind. Given that he has this basic knowledge, the doctor's next task is to find the facts and to evaluate the clinical situation as it develops from day to day throughout the illness. In this he has science and technology among his tools, and he must know how to use them, but he will often find that the evaluation and judgment of the human mind far outweigh the value and accuracy of scientific measurement; and, of course, he requires other qualities, of understanding, insight, interpretation, compassion, and a carefully practised technique, without which the very facts on which he can base a reasoned plan of action will elude him, for they will not cross the barrier between him and the patient's mind. There is, of course, nothing which denies the clinical scientist of these qualities.

In the enthusiasm for teaching principles, the fact that much of medicine depends on the acquisition of technique is some-

times overlooked. Technique can be crucial where academic knowledge is useless. I wonder if Paganini ever realized that he was playing on a logarithmic scale; or cared.

To use the new aids which science has now put at his command the doctor does not have to know the scientific principles from which they have developed; and as science advances and becomes more complex it becomes increasingly impossible for him to do so. This should be accepted by medical educators without guilt or shame. The modern physician does not have to learn the engineering and physical principles on which an x-ray machine is constructed or the chemical nature of the emulsions used on the film in order to interpret an x-ray picture. (Even the interpretation is usually done for him.) He does not have to be a physicist to read an electrocardiogram. Almost none of the physicians who daily prescribe the tetracycline group of drugs knows anything about their chemical structure; or cares. Science is throughout the servant, not the master, a servant to be used with understanding and called on unsparingly in the patient's interest, but dismissed peremptorily and without remorse on all those many occasions when the patient is better off without its services; not only when science becomes a mere intruder in private affairs, but when it has led only to false clues, and the imperative need is to go back to the intimate confrontation of the patient for the information which he alone can give.

This should not mean that the doctor is disinterested in discovery, in the use of new remedies, or in the proper scientific appraisal of all that he does. Indeed, he should welcome the opportunities which scientific medicine presents in these respects; but I believe it to be more difficult to teach the true aims and values of the practice of medicine to undergraduate students from a department in which the primary aim is too obviously research and discovery, in which science has become the master. I know that there will be many who do not agree with me and who see no conflict and no antithesis between the aim of the good doctor and that of the good scientist. They will make the point that when a patient is seriously ill his foremost need is to be under the care of whoever has most knowledge of his kind of illness. This ingenuous view, which at first seems self evident, implies that someone else has first selected the right patient for the right department, and, secondly, that the illness is amenable to treatment or relief by modern medical science and not solely to diagnosis and investigation. "Guérir quelquefois, soulager souvent, mais rechercher toujours."

What is, of course, true is that the same man may wear the mantle of the doctor or that of the scientist with equal grace at different times and occasionally at the same time. Nevertheless, I think that this does not come easily to all people at all times, and such evidence as we have from John Aubrey and Lord Conway and other sources strongly suggests that Harvey himself found the compromise a difficult one. Lord Conway's letter of 1651 to his daughter, who was Harvey's patient, says: "I hear that you have a great opinion of Doctor Harvey. I thinke you doe well to love and respect a person of his merite for I thinke he hath deserved extremely well of all learned men for what he hath found out . . . but in the practice of Physicke I conceive him to be to much governed by his Phantasy . . . To have a Physician abound in phantasie is a perilous thing. . . ."

Conclusions

You will see, Mr. President, that I think the clinical scientist has certain difficulties which do not present themselves to the non-clinical scientist in medical research. I also believe that clinical science in its present state of development has neglected some of its opportunities, and has shown an unfortunate tendency to follow only the methods of physical science, which try to prove everything by contrived experiment, to the neglect of discovery by deliberate and relevant observation and the kind

of evolutionary—or, if you like, teleological—thinking so necessary to the study of biology. For in biology, because of Darwinian selection, we are entitled to ask not only "What?" and "How?" as in physical science, but also "Why?" and "What for?"

Because in clinical science we pride ourselves that we are building up medical knowledge we should not complacently assume that we are always doing it the right way, or making the best use of resources which in any society are bound to be limited. We should remember with John Aubrey that "Pride has been one of the greatest stoppers of the Advancement of Learning."

The defects may be only part of a temporary chapter in the history of medicine, and a symptom of a more widespread ailment. For man has put most of his efforts into improving the material state of society (and perfecting the engines of war), and has given scant attention to the ills of the mind of man and woman, and the study of their behaviour in health and disease and in society.

I know that I have spoken some heresies. If they are rather disturbing ones, my personal researches lead me to believe that the defences of the clinical scientists will be equal to them. Perhaps for another few years.

Nevertheless, with Harvey, "I fear lest I have mankind at large" (or at any rate some of my colleagues) "for my enemies, so much doth wont and custom become a second nature. Doctrine once sown strikes deep its root . . . Still the die is cast and my trust is in the love of truth and the candour of cultivated minds."

Factors Affecting the Response to Clomiphene Therapy

DAVID FERRIMAN,* D.M., F.R.C.P.; ANTHONY W. PURDIE,† M.R.C.P.GLASG., F.R.C.S.GLASG., F.R.C.O.G.
 MICHAEL CORNS,‡ M.SC.

Brit. med. J., 1967, **4**, 444–446

It has been well established that clomiphene citrate (Clomid), a compound allied to chlorotrianisene (Tace), is capable of inducing ovulation in a substantial proportion of patients suffering from anovulatory infertility, with consequent relief of infertility in a significant number. In the present study we attempt to determine factors concerned with the outcome of such therapy.

Material and Methods

Fifty-five patients attending one gynaecological and one endocrine clinic with amenorrhoea, severe oligomenorrhoea, or mild oligomenorrhoea with anovulatory cycles have been treated with clomiphene. Forty-one of them were also suffering from infertility or amenorrhoea of more than two years' duration. All the patients had a full medical and gynaecological examination to exclude medical or gross gynaecological disorders likely to be associated with menstrual disturbance or infertility. All kept a basal temperature chart for at least six months, often much longer, before treatment, and continued to do this throughout therapy. Gynaecography was performed in 51. In those with infertility endometrial curettage and culture for *Mycobacterium tuberculosis*, hysterosalpingography, and analysis of the husbands' seminal fluid was carried out. Follicle-stimulating hormone assays were not done, but primary ovarian disorder is thought to have been unlikely on clinical grounds.

Oestrogen excretion assays were carried out on 39 patients, both under basal conditions and after treatment with clomiphene. At first, assays were done at weekly intervals for one

month after the start of treatment; experience showed that oestrogen responses tended to be maximal between the second and third weeks, and in the later stages of the investigations assays were performed only on specimens obtained during this period. Total oestrogen assays were made with a modified form of Ittrich's method (Corns and James, 1967), which had a non-specific fluorescent background of 10 µg./24 hours.

Various dosage schedules have been used, ranging from 50 mg. b.d. for five days to 100 mg. b.d. for two weeks. No obvious advantages were found for the longer schedules, and eventually a standard dosage of 100 mg. b.d. for five days was used. All patients were given at least three courses of treatment before it was concluded that no benefit was to be obtained.

Results

Criteria Used in Evaluation of Results.—Three types of response to clomiphene were distinguished: (1) no response, (2) menstruation without ovulation (as evidenced by absence of progestational temperature rises), and (3) ovulation and menstruation. Examination of our data suggested that the most meaningful classification would be into those with and those without evidence of ovulation. The criterion used for the diagnosis of polycystic ovaries was a gynaecography index exceeding 21 (Ferriman and Purdie, 1965).

Ovulatory Response in Relation to Duration of Cycles.—Consideration of our findings suggested that a significant division would be into patients with menstrual cycles less than or exceeding six months. The data have been analysed accordingly and the results are shown in Table I. Clearly patients with cycles of less than six months' duration fared better than those with cycles exceeding this figure. The difference is highly significant at the 0.1% level ($\chi^2 = 12.40$).

Ovulatory Response in Relation to Basal Oestrogen Excretion.

—The Chart relates basal oestrogen excretion for each patient to the increments of oestrogen excretion after clomiphene therapy and the presence or absence of an ovulatory response. Scrutiny suggests significant dividing lines between basal oestrogen excretions above or below 21 $\mu\text{g.}/24$ hours, and between increments of oestrogen excretion above and below 40 $\mu\text{g.}/24$ hours. Patients with basal excretions below 21 $\mu\text{g.}/24$ hours generally have increments of excretion below 40 $\mu\text{g.}/24$ hours and lack of ovulatory response. Patients with basal oestrogen excretions above 21 $\mu\text{g.}/24$ hours generally have increments of excretion above 40 $\mu\text{g.}/24$ hours and an ovulatory response. Several patients show high increments of excretion without ovulation, though usually with menstruation. Others show ovulation with low increments of excretion; examination of basal temperature charts showed that this was invariably caused by failure to collect specimens for assay during the progestational phase, a defect in our experimental design. The data are set out in Table II. The tendency for ovulatory response to be related to higher basal oestrogen excretion is clear, and the figures approach significance at the 5% level ($\chi^2=3.582$ by Yates's method; Maxwell, 1961).

Ovulatory Response in Relation to Ovarian Size.—Table III shows ovulatory response in patients with normal and polycystic ovaries. It is clear that patients with polycystic ovaries

fare better than those with normal ovaries. The difference is very significant at the 1% level ($\chi^2=7.498$).

Ovulatory Response in Relation to Duration of Cycles and Ovarian Size.—The data relating ovulatory response to duration of cycles have been broken down into groups with normal and polycystic ovaries in Table IV. The same tendency for patients with cycles of less than six months' duration to fare better than those with longer cycles is shown in both groups, though this is much more pronounced in patients with normal-sized ovaries than in those with polycystic ovaries. Patients with polycystic ovaries noticeably predominated in the group with cycles of less than six months' duration, and those with normal-sized ovaries noticeably predominated in the group with longer cycles; this is very significant at the 1% level ($\chi^2=10.283$).

Conception.—Nine out of the 41 patients complaining of infertility conceived. Five have successfully gone to term and three were still pregnant at the time of writing. Pregnancy in the ninth ended in abortion. One of the patients subsequently going to term had an abortion after an earlier course of clomiphene.

Table V shows the incidence of conception in patients with normal and polycystic ovaries. Clearly, patients with normal ovaries fared better than those with polycystic ovaries. The figures approach significance at the 5% level ($\chi^2=3.197$ by Yates's method; Maxwell, 1961).

Discussion

Our classification of response to clomiphene based upon basal temperature charts and the occurrence or otherwise of menstruation complement the findings of Bell and Loraine (1966), based on steroid excretion studies. These workers found three types of response: (1) no change in oestrogen nor in pregnanediol excretion; (2) a rise in oestrogen but none in pregnanediol excretion; and (3) a rise in both oestrogen and pregnanediol excretion similar to that found in the normal menstrual cycle.

Our finding that patients with basal oestrogen excretion levels exceeding 21 $\mu\text{g.}/24$ hours respond better than those with lower excretion levels is very similar to findings reported by Bell and Loraine (1966) and Townsend *et al.* (1966), bearing in mind the nonspecific background fluorescence of 10 $\mu\text{g.}/24$ hours found in our method.

Our group of patients with menstrual cycles of less than six months' duration contain a marked preponderance with polycystic ovaries, while the group with cycles of more than six months' duration contain a marked preponderance of normal-sized ovaries. The explanation in the present state of knowledge can only be conjectural. If one postulates an underlying disturbance of hypothalamic centres governing gonadotrophin production, the milder forms of the disorder may have some

residual follicle stimulating hormone secretion leading to the production of polycystic ovaries (Ferriman, 1960); all follicle stimulating hormone secretion may have disappeared in the more severely affected patients. The development of sensitive and precise radio-immunological assays for gonadotrophins may shed some light on the problem before long.

The incidence of conception in our series (9 out of 41) is higher than we would have anticipated from our previous experiences in the field. This has been the experience of many other workers (Greenblatt, 1966). It is not possible to make a precise statistical assessment of the comparative value of this drug in the absence of control data. The provision of such data would be of great interest.

It is odd that while patients with polycystic ovaries show a better ovulatory response to clomiphene than those with normal-sized ovaries their conception rate should be lower. Perhaps the thickened capsules of the polycystic ovaries interfere with the release of ova, or the increased production of androgen by these ovaries impairs nidation.

Summary

The ovulatory response to clomiphene is significantly better in patients with menstrual cycles of less than six months' duration compared with those whose cycles exceed this figure, and

in patients with polycystic ovaries compared with those whose ovaries are of normal size. It is better in patients with basal oestrogen excretions exceeding 21 $\mu\text{g.}/24$ hours than in those whose excretion levels fall below this figure (obtained by a method having a nonspecific background fluorescence of 10 $\mu\text{g.}/24$ hours), though the difference does not quite reach formal significance.

Patients with normal-sized ovaries conceive more readily than those with polycystic ovaries. The difference does not quite reach formal significance.

We wish to thank Dr. D. Mansell-Jones and Dr. J. P. Birkett, of Merrell-National, for supplies of Clomid and for a generous grant towards expenses; Dr. W. G. Dangerfield for laboratory facilities; Mrs. F. Norris for statistical analyses; and Miss S. Ferriman and Miss E. Whiteley for preparation of the diagram.

Brit. med. J., 1967, 4, 446-449

When mechanical or anatomical lesions are excluded, disturbances of ovulation and corpus luteum function represent the main cause of infertility.

The factors which disturb the proper function of the reproductive system from within may stem from any of the participating cells or populations of cells in the central nervous system, the pituitary gland, the ovary, or perhaps even the uterus. These factors may involve faulty stimulation (abnormal magnitude, sequence of appearance, or time of action of stimuli) or faulty response of the target cells or organs. Each and every one of these factors, if sufficiently powerful, or when acting long enough, may lead to an imbalance of the hormonal feedback mechanism and consequently to impaired fertility. In the majority of cases some absolute or relative primary or secondary abnormality in the nature or magnitude of gonadotropic stimulus exists, regardless of the primary cause. A convenient simplification is to divide these patients into two groups: those with gonadotropic insufficiency due to primary failure in production of gonadotrophins, and those with abnormal gonadotropic stimulus due to disturbed release of gonadotropic hormones.

Preparations of human gonadotrophins and clomiphene citrate have proved to be of definite value in the treatment of these two groups of patients.

Recently gonadotropic extracts from human post-mortem pituitaries and human menopausal urine have been made available for clinical use. These preparations in conjunction with human chorionic gonadotrophins have proved capable of inducing ovulation. Numerous pregnancies have resulted from such treatment (Gemzell, 1966; Lunenfeld and Donini, 1966; Shearman, 1966; Rabau *et al.*, 1967). It was shown by Crooke *et al.* (1963) and Diczfalussy *et al.* (1964) that gonadotropic preparations derived either from human post-mortem pituitary glands or from postmenopausal urine, administered to the same patients, provoked a similar response as judged by steroid excretion patterns and by vaginal or endometrial morphology.

Another approach to the treatment of anovulation was made possible by the introduction of clomiphene citrate (MER-41). This synthetic non-steroid preparation is a derivative of chlorotrianisene (TACE) and possesses both oestrogenic and anti-oestrogenic properties (Greenblatt, 1966). The exact mechanism of action of clomiphene in inducing ovulation is as yet unclear. Since urinary excretion of gonadotrophins was reported to be increased during or immediately after administration of clomiphene (Dickey *et al.*, 1965), it has been suggested that the drug acts either directly or indirectly on

* Department of Obstetrics and Gynaecology, Tel-Hashomer Government Hospital and Tel Aviv University Medical School, Tel Aviv, Israel.

† Institute of Endocrinology, Tel-Hashomer Government Hospital and Tel Aviv University Medical School, Tel Aviv, Israel.

the release of gonadotropins. There is, however, no general agreement whether clomiphene causes the release of follicle-stimulating hormone (F.S.H.) (Kistner, 1966), luteinizing hormone (L.H.) (Igarashi *et al.*, 1967), or both (Dickey *et al.*, 1965). Whatever the exact nature of its action, clomiphene citrate has been shown capable of inducing ovulation in certain types of anovulatory patients (Johnson *et al.*, 1965; Greenblatt, 1966; Kistner, 1966; Serr *et al.*, 1966; Shearman, 1966).

Principles and Results of Treatment

Human gonadotropins or clomiphene citrate were administered to 235 patients through 761 courses of treatment. The patients were divided into two main groups according to the level of gonadotropins and to the endogenous oestrogen activity as judged by urinary oestrogen, vaginal smears, cervical mucus, and/or occurrence of withdrawal bleeding following administration of medroxyprogesterone acetate (MAP).[‡] The two main groups were subsequently subdivided according to the clinical signs, such as amenorrhoea and other ovulatory disturbances as outlined in Table I. Patients who had low

TABLE I.—Number of Cases and Treatment Courses in Various Groups of Patients With Ovulatory Failure

Polycystic ovary syndrome (histologically proved)	6	29
Anovulation with fairly regular cycles	31	83
Group III (corpus luteum insufficiency)	46	302
Total	235	761

urinary gonadotropins and no detectable oestrogenic activity were treated by human gonadotropins; those with urinary gonadotropins within the normal range and evidence of endogenous oestrogen activity (MAP-positive) were given either gonadotropic preparations or clomiphene citrate; cases diagnosed as corpus luteum insufficiency were treated with clomiphene only, and formed a separate group (group III).

Dosage, Treatment Schedules, and Results of Gonadotropic Treatment

Human menopausal gonadotropin (H.M.G.)[§] having both follicle-stimulating and luteinizing activities was used. Each ampoule of the preparation contains approximately 75 i.u. of F.S.H. and 75 i.u. of L.H. Each treatment course was scheduled according to the patient's individual response. Treatment was started with H.M.G. (Pergonal) at a dose varying from 1 to 4 ampoules per day. Follicle maturation and oestrogen secretion were evaluated from urinary oestrogen levels, crystallization of cervical mucus (ferning pattern), the appearance of external cervical os, vaginal smears, and ovarian size. Treatment was continued until oestrogen secretion, as evidenced by the response of these target organs, was somewhat greater than during the peak of a normal preovulatory phase.

[‡] Progestational agent with no intrinsic oestrogenic activity.

[§] Supplied as Pergonal by Istituto Farmacologico "Sersono," Rome, Italy, and later by Ikapharm, Ramat-Gan, Israel.

Administration of human chorionic gonadotropin (H.C.G.)^{||} was then started. Pergonal was usually continued during the first two days of H.C.G. administration, which was given in a dose of 5,000–10,000 i.u. daily for three to four days. The patients were instructed to have intercourse on each of these days.

Diagnosis of ovulation was regarded as proved only if pregnancy ensued. The occurrence of ovulation and the presence of a functioning corpus luteum were, however, presumed on the basis of the following criteria: basal body temperature shift, progestational changes in vaginal smears, disappearance of previously strong positive ferning pattern, urinary pregnanediol excretion of at least 2 mg./24 hours, secretory changes in the endometrium, and menstrual bleeding appearing 13±2 days after the presumed day of ovulation.

Table II shows the results of sequential H.M.G.-H.C.G. therapy. Most of the patients responded to treatment with doses varying up to 50 ampoules of Pergonal and 25,000 i.u. of H.C.G. Only in a few cases were higher doses needed to produce the desired effect. Statistical evaluation showed a significant correlation between the nature of the hormonal disturbance and the quantity of H.M.G. required for ovulatory response. Patients with amenorrhoea needed significantly more Pergonal than those with follicular phase disturbances (oligomenorrhoea) and anovulation ($P<0.001$). Whether these differences in response were caused by differences in ovarian sensitivity to gonadotropins or were related to the effect of the patient's endogenous feedback mechanism is as yet unknown.

TABLE II.—Results of Sequential H.M.G.-H.C.G. Treatment in 134 Patients (1961–6)

	No. of Cases	No. of Courses	Courses per Patient	Presumed Ovulation		Pregnancy		
				No.	% of Courses	No.	% of Patients	% of Courses

Total	134	256	1.9	224	87.5	80	60.0	31.3

The overall abortion rate after treatment with H.M.G. and H.C.G. was 24%. Mild adverse reactions were noted in 4.2% and severe reactions (hyperstimulation syndrome) in 2.8% of patients. A detailed description of adverse reactions was reported elsewhere (Mozes *et al.*, 1965; Rabau *et al.*, 1967).

Dosage, Treatment Schedules, and Results of Clomiphene Treatment

One hundred and one patients were treated through 505 courses (Table III). The criteria of positive response were identical with those employed in gonadotropic treatment. As to the dosage schedules, numerous authors (Naville *et al.*, 1964; Dickey *et al.*, 1965; Kistner, 1965; Pildes, 1965; Serr *et al.*, 1966; Shearman, 1966) pointed out that lower dosage and shorter treatment resulted in a decrease of more serious side-effects related to ovarian overstimulation, while the overall pregnancy rate remained unaffected.

^{||} Supplied as Chorigon by Ikapharm, Ramat-Gan, Israel.

We generally start with a dose of 50 mg. of clomiphene daily for seven consecutive days. Only those patients who do not respond to this dosage (with either rise in basal body temperature or increase in urinary pregnanediol) are given 75 mg. daily for seven days. Those who still do not respond are then given a trial course of 100 mg. daily for the same length of time. If two trials with this latter regimen are ineffective the patient is classified as unsuitable for clomiphene therapy and is scheduled for treatment with human gonadotropins. Gonadotropic treatment after failure to respond to clomiphene has been used so far in five patients. Two of them conceived.

* Proved by histology.

The overall abortion rate in patients treated with clomiphene was 20.6%. No serious adverse reactions were noted.

Discussion

Disturbance of ovulation is one of the main causes of sterility. The use of sequential H.M.G.-H.C.G. therapy and of clomiphene enabled induction of ovulation in a considerable number of anovulatory patients. A prerequisite condition for successful induction of ovulation is the presence of ovaries capable of response to stimulation. Therefore patients with ovarian agenesis or dysgenesis or with menopausal-like ovaries are unsuitable for this treatment. Since the action of clomiphene is mediated through the pituitary, in patients treated with this agent the presence of a pituitary gland capable of synthesizing gonadotropins is essential. We have divided patients with anovulation into two groups: those with primary failure in production of gonadotropins, and those with abnormal gonadotropic stimulus due to disturbed release of gonadotropic hormones. The latter condition may be caused either by a defect in the pituitary-hypothalamic complex or by abnormal ovarian feedback mechanism. Patients in group I present with primary or secondary amenorrhoea, low or undetectable gonadotropins, and absence of endogenous oestrogen production. Patients in group II have gonadotropins in the normal range (sometimes low), secondary amenorrhoea, oligomenorrhoea or anovulatory cycles, and evidence of endogenous oestrogen production. In group I cases substitution therapy by H.M.G. and H.C.G. is needed. Patients in group II may be treated with human gonadotropins or with clomiphene with a very similar success rate.

Since pregnancy is the main goal of treatment and the only unequivocal sign of ovulation, the results of treatment with human gonadotropins or with clomiphene should be analysed in relation to the pregnancy rate. Such an analysis shows that in our material sequential H.M.G.-H.C.G. therapy gave the

best results in patients of group I, and the pregnancy rate obtained in group II was somewhat lower (65% and 44.1% respectively). The mean percentage of treatment courses resulting in pregnancy was significantly higher in group I (34.4) than in group II (22.4). The lower pregnancy rate in this latter group was due mainly to the poor results obtained in patients with anovulation associated with fairly regular menstrual cycles. However, it should be pointed out that these patients responded well to clomiphene treatment—53.3% of pregnancies. It might be speculated that in these cases the patient's feedback mechanism interferes unfavourably with gonadotropic treatment. Clomiphene, allowing a more flexible interplay between gonadotropic release and ovarian feedback, provides better results.

The overall results of clomiphene treatment in group II were similar to those obtained by gonadotropic therapy, 49.0% and 44.1% pregnancies respectively. It should be noted, however, that clomiphene required more treatment courses than sequential H.M.G.-H.C.G. administration. The mean number of courses per patient was 3.7 in clomiphene treatment and 1.9 in gonadotropic therapy. The percentage of treatment cycles resulting in pregnancy was 13.3 and 22.4 in clomiphene and gonadotropic therapy respectively. This may be due to the simpler but more rigid dosage scheme used in clomiphene treatment as compared with the flexible, individually adjusted treatment schedule of gonadotropic therapy.

Our results with clomiphene treatment show a pregnancy rate higher than that reported by other authors (Bishop, 1965; Johnson *et al.*, 1965; Beck *et al.*, 1966; Greenblatt *et al.*, 1966). This is probably due to preselection of patients.

In group III (corpus luteum insufficiency) clomiphene gave rather poor results. Pregnancy was achieved in only 15.2% of patients and in 2.3% of treatment courses. Sequential H.M.G.-H.C.G. given to a few patients produced even poorer results. Patients in this group differ from those in groups I and II because they show indirect signs of ovulation such as a rise in basal body temperature, disappearance of previously positive ferning pattern, progestational effect in vaginal smears, and some degree of secretory changes in the endometrium. Urinary pregnanediol excretion is above 1 mg./24 hours but rarely reaches normal values.

Oestrogen deficiency found in some of these patients during the follicular phase suggests that at least a part of this group represent anovulation with luteinization of unruptured follicles, rather than ovulatory cycles with insufficient corpus luteum function. It might be speculated that in these patients the disease is due to faulty response of the ovaries to gonadotropic stimulation. Detailed investigations of this group of patients are in progress.

On the basis of presented data it may be concluded that treatment with human gonadotropins and with clomiphene citrate is highly effective in sterility due to anovulation. When the patients are carefully selected for suitable treatment an overall pregnancy rate of 57% may be expected.

Summary

A series of 235 patients with infertility due to disturbances of ovulation were treated with human gonadotropins or with clomiphene citrate. The patients were divided into two main groups according to the level of urinary gonadotropins to the endogenous oestrogen activity. Patients with corpus luteum insufficiency formed a separate group. Group I (low urinary gonadotropins, no evidence of endogenous oestrogen activity) comprised 100 patients with primary, secondary, or postpartum amenorrhoea. Group II (gonadotropins in normal range, evidence of endogenous oestrogen activity) included 89 patients with secondary amenorrhoea, oligomenorrhoea, or anovulatory cycles. Forty-six patients with corpus luteum insufficiency formed group III.

‡ Generously supplied as Clomid by Wm. Merrell Co., U.S.A., and later as Ikaclomin by Ikapharm, Israel.

Patients of group I were given sequential H.M.G.-H.C.G. therapy, those of group II received either gonadotropins (34 cases) or clomiphene (55 cases), and those of group III were treated with clomiphene only.*

Gonadotropic therapy gave better results in patients of group I than in those of group II (65% and 44.1% of pregnancies respectively). In group II patients gonadotropins and clomiphene gave similar results (49% and 44.1% pregnancies respectively). The results in group III were poor (15.2% of pregnancies).

When patients are carefully selected for suitable therapy, sequential H.M.G.-H.C.G. or clomiphene therapy provides an overall pregnancy rate of approximately 57%.

Three Swedish Families with Porphyrria Variegata*

B. HAMNSTRÖM, M.D.; B. HAEGER-ARONSEN, M.D.; J. WALDENSTRÖM, M.D., F.R.C.P.; B. HYSING, M.D.
J. MOLANDER, M.D.

Brit. med. J., 1967, 4, 449-453

The interest in porphyrins and porphyria diseases has increased considerably during the last decades. This fact is probably partly due to the great progress made in porphyrin chemistry during that time.

In Sweden porphyria acuta intermittens (PAI) is predominant among the diseases with disturbances in the porphyrin metabolism. One of us (Waldenström) has studied this disease and its spread in our country during the last 35 years. About 600 cases are now known, half of them still living. Careful genetic studies have revealed a non-sex-linked inheritance of Mendelian dominant type. Clinically the classical symptoms are, first, severe abdominal pain which may lead to operations with fatal outcome; psychiatric symptoms, varying from short periods of confusion to severe psychosis, where sedating drugs aggravate the state; and neurological manifestations such as coma or epileptic fits, and above all pareses, including respiratory paralysis, which has often been the cause of death. We do not know of any clear-cut PAI patient with light-sensitivity. Chemically the typical findings in PAI are increased urinary excretion of porphyrin precursors—that is, porphobilinogen (PBG) and δ -aminolaevulinic acid (ALA). The disease has therefore been designated as pyrrholia or pyrrholoporphyrria. The latent cases were found by analysis of PBG in the urine (Waldenström, 1937). The faecal excretion of porphyrins is only slightly increased or not at all increased (Haeger-Aronsen, 1962). The absence of preformed porphyrins inside the body has been regarded as the explanation of the lack of light-sensitivity.

Among the white population in South Africa a great number of patients have been shown to have a special type of porphyria (Dean, 1953; Dean and Barnes, 1955, 1958; Eales, 1956, 1960). Clinically, all the symptoms typical of PAI may be present, often with light-sensitivity. In many cases only the skin is affected. As in PAI, the inheritance is dominant, non-sex-linked. Because of the varying symptoms the disease was given the name porphyria variegata (PV) by Dean and Barnes (1959). The best way to find the latent cases of this disease is to analyse the faecal excretion of porphyrins, which is almost always markedly increased. It has been claimed that only during the acute stage is the PBG and ALA excretion in the urine pathologically increased. At first the difference between PAI and PV regarding cutaneous symptoms was supposed to be due to the higher intensity of sunlight in Africa. However, the different biochemical characteristics mentioned above and the appearance of PAI in South Africa with signs and symptoms quite typical and without genetical connexion with PV (Dean, 1963) supported the earlier opinion of Waldenström that PAI and PV were two different gene defects. Dean and Barnes (1959) confirmed this statement once and for all.

Earlier, 13 Swedish cases from four different families with porphyria variegata or protocoproporphyrria were reported (Waldenström and Haeger-Aronsen, 1963). We suspected that these cases, of which five were latent, represented PV, since one from each family suffered from light-sensitivity and several cases had considerably higher faecal excretion of porphyrins than is usually seen in PAI. The only case which fulfilled all the criteria so completely that the diagnosis PV could be made with certainty was that of a Danish woman (Case 3).

* From the Departments of Medicine in Karlstad, Malmö, and Ängelholm, Sweden.

Material and Results

Our material consists of 24 cases occurring in three families (Figs. 1-3). Two of the families (A and B) were descended from Småland, in the southern part of Sweden. Genetical studies tracing the ancestors back to the middle of the nineteenth century failed to reveal any blood relationship between these two families or with any families having acute porphyria intermittens. The third family (C) is of particular interest because of its origin from the Skellefteå area, on the Gulf of Bothnia, where most PAI patients live. Some of the ancestors have been traced back to the end of the eighteenth century, but no relationship to the PAI families has been found. The so-called church books have, however, been partly destroyed by fire, and so the genetical studies have not been completed.

Case Reports

Family A. Case III:3.

House painter, born in 1937. During 1952 to 1955 he indulged heavily in alcohol, but since then has always been sober. He married in 1958. From that time he began to feel more nervous than previously, probably partly because of domestic problems. In 1960 he took eight tablets of Diminal (butenemal + allypropymal), possibly with suicidal intention. He had to stay in hospital for one day, and was then discharged in good shape. In 1960-3 he consulted several doctors because of his nervousness and was prescribed sedatives in the form of meprobamate, with barbiturates and especially Mebumal (pentobarbitone B.P.), of which he took 0.10-0.15 g. almost every evening during long periods. In September 1961 he had acute pains in his arms and particularly in the thumbs. The pain was deeply located, totally independent of effort, and of a

FIG. 3.—Family C, with porphyria variegata.

continuous, very unpleasant character. The muscles were not tender. The pains disappeared spontaneously but sometimes returned later. In the summer of 1962 the patient noticed sensitivity to light for the first time. Because of his profession his hands had often to be in the sunshine during the summer, and blisters developed on the backs of them. The blisters ulcerated, and not until the autumn did they heal, with scars and pigmentation (Fig. 4). The skin was also rather sensitive to mechanical trauma. In the summer of 1963 the skin symptoms returned and were located in his face.

For many years the patient had had epigastric discomfort resembling acid gastritis (some of his brothers and sisters had the same symptoms without being carriers of the PV gene). In the autumn of 1962, when there was a sharp marital conflict, he had particu-

FIG. 4.—Hands of Case A, III:3.

larly severe abdominal pains, which led to increased drug consumption. He at last called in a doctor, and went to the hospital surgical ward with the diagnosis of *ulcus penetrans* (?). He could not distinguish between the gastralgia and these new pains—no doubt explained by his porphyria—in any other way than that the latter were more severe and much more continuous. At the hospital, where he was admitted on 3 December 1962, the pains disappeared after a few days; and a confusion state with hallucinations developed. Later the patient remembered that he thought the hospital was on fire, which he could see and smell. The psychotic symptoms were so severe and he was so agitated that on 10 December he was sent to a mental hospital; there he soon improved.

During the first few days in the hospital he was given barbiturates, but from 8 December only chlorpromazine was prescribed.

The colour of his urine was always normal. The diagnosis porphyria variegata (see Table) was suspected by one of us (Hamnström) and fully confirmed by the laboratory data.

Urinary Excretion of δ -aminolaevulinic Acid (ALA), Porphobilinogen (PBG), Uroporphyrin (UP), and Coproporphyrin (CP) and of Faecal CP and Protoporphyrin (PP) in 24 Patients from 3 Families with Porphyria Variegata

* L = latent. † M = manifest.

The patient left the hospital in a good condition. During the late spring of 1963 he began to work outdoors again, but his skin condition was aggravated, and he had very severe abdominal pains. He knew the risks of barbiturates, and has denied having taken such medicine after 1962. Since that time he could not take alcohol either, because it caused abdominal pains.

In July 1963 he again developed confusion. He was sent to hospital, where he spent nine days without receiving any barbiturates and was discharged in a good condition. Since then he has not had any abdominal or psychiatric crises, nor has he shown any neurological symptoms. His physical status was always mainly normal. His blood pressure, for example, was almost normal, and he had had no tachycardia, not even in the acute stage of the disease. Routine blood analyses showed nothing abnormal. In the acute stage, however, an increased activity of serum alanine aminotransferase and serum aspartate aminotransferase to a maximum of 204 units and 142 units respectively was registered. Later the transaminases became normal.

Analysis of urine and faeces from 41 of the proband's relatives was performed. It was then found that the patient's father (Case II:3), two of the father's sisters (Cases II:1 and II:4), one of the father's brothers (Case II:2), and two cousins (Cases III:1 and III:2) were also carriers of the porphyria variegata trait (see Table). As they had never had any symptoms typical of porphyria variegata they were considered to be latent cases. The grandmother who died in 1950 was said to have had a vesicular dermatitis occasionally on the back of her hands. Maybe she also was a carrier of the gene.

Family B. Case IV: 2.

Housewife, born in 1932. Up to 1960 she had always been in good health. She had had three pregnancies during 1951–6 without any complications. Since 1960 she had been nervous and irritable periodically. In November 1962 she started to use barbiturates during these occasions. In early December of the same year she was taken ill with abdominal pains, restlessness, and insomnia. She increased her barbiturate consumption but became rapidly worse, with pains and numbness in her extremities. She also felt sick and began to vomit. On 20 December she was admitted to the obstetrical and gynaecological department of Ångelholm. There she was found to be in the sixth week of gestation, and was dehydrated and mentally confused. After some days' treatment with chlorpromazine, water, and electrolytes she rapidly improved, but was mentally exalted and unstable during her stay at the hospital. At her own request she left the hospital on 24 December, and while at home continued to take barbiturates. Because of ill-health she was readmitted after 24 hours at home. It was noticed that her urine was dark brown. As acute porphyria intermittens was suspected, a PBG analysis was made on her urine. Since the excretion of this metabolite was markedly increased the suspected diagnosis was regarded as confirmed.

On admission she was mentally lucid, but she complained of double vision and severe pains in her extremities and abdomen. Her reactions bore witness to her agony and she could not lie still. Neurological examination revealed normal conditions. The electrocardiogram showed sinus tachycardia but was otherwise normal. Her blood pressure was 160/100 mm. Hg. Routine blood analyses were mainly normal with the exception of a moderate hypochromia (Hb 11.2 g./100 ml., R.B.C. 4.1 mill./cu. mm.) and a slightly increased serum alanine aminotransferase (56 units). For analyses of porphyrins and their precursors in urine and faeces see Table.

She was treated with adrenocorticotrophic hormone, chlorpromazine, and morphine. During this treatment she rapidly felt better. On 9 January 1963 she had fully recovered and left the hospital. It was then discussed whether she would be allowed to continue her pregnancy, but as the patient herself was very eager to do so and she had had three pregnancies without any complications, she was allowed to continue it.

She was well until the 32nd week (July 1963), when she had to be taken to hospital because of intense itching. She had scratches all over her body and symptoms which, according to the consultant dermatologist, seemed to be a dermatitis artefacta. She had no icterus. The scratches as well as the itching disappeared rapidly on symptomatic therapy. The analyses of ALA and PBG are given in the Table.

On 12 August 1963 the patient gave birth, without any complications, to a well-shaped girl, weighing 4,350 g. Since then she has felt well with the exception of some short periods with slight colicky pains.

On analysing the urine and faeces of 26 of the proband's relatives for porphyrins and their precursors, we found another eight cases with pathological excretion of porphobilinogen (see Table and Fig. 2). These cases were: the sister (Case IV:3), the mother (Case III:1), one uncle (Case III:2), one aunt (Case III:3), one brother (Case IV:4), and three cousins (Cases IV:1, IV:5, and IV:6). The latter seven were clinically free of symptoms and consequently were regarded as latent cases, while the sister had had some troubles of colicky type, until then unaccountable, and she was therefore regarded as a manifest case of acute intermittent porphyria. Case IV:1 is especially interesting, as his father, who must be a carrier of the PV trait, seems to have a normal porphyrin metabolism with a normal urinary and faecal excretion of porphyrins. This we have never found in carriers of the PAI trait (Waldenström and Haeger-Aronsen, 1964).

Family B. Case IV: 3.

This patient, born in 1938, was an unmarried practical nurse in a nursing-home. During childhood she had frequent bouts of unexplained colicky pain in the left side of her abdomen. She had no recollection of dark urine during these bouts. In November 1964 she was admitted to the gynaecological clinic because of pains in the lower abdomen. Abrasio mucosae uteri was performed. Three days later she experienced severe abdominal pains. A left-sided gonorrhoeic salpingitis was diagnosed and treatment with antibiotics was started.

In January 1963 the patient's ALA and PBG excretion had been checked when her sister's (Case IV:2) porphyria was discovered. The excretion was at that time abnormally high, and when rechecked during the current hospitalization the excretions were again found to be very high (see Table). The patient was therefore admitted to Malmö General Hospital. On admission she was nauseated and complaining of pains in her abdomen, the heart rate was 90–100 beats/min., and she vomited frequently. Because of her sister's diagnosis she was thought to suffer from the same condition. When, however, one of us (Waldenström) examined the patient the day after admission several blisters and scars on the back of the hands, the forehead, and the nose were discovered. It was then suspected that she suffered from PV rather than PAI. This was confirmed when the excretion of porphyrins in the stools was found to be raised to a level never seen in PAI (Haeger-Aronsen, 1962).

During the past few years the patient has had shorter periods of colicky pains and, especially during the summers, there have been several blisters on her hands. Her family think that she has become a little more nervous.

An appointment was made with the sister (Case IV:2), whom we had not seen earlier at Malmö. On physical examination she too was found to have blisters and scars on her hands and nose. She reported spontaneously that her skin had become more brittle during recent years, and she also was subsequently found to have high amounts of porphyrins in her stools.

Family C. Case V: 2.

This man, an unmarried machinist born in 1922, had been healthy up to the age of 18, when he was admitted to hospital because of aching pains in the lower quadrants of the abdomen, nausea, and vomiting. On admission the abdomen was soft and the urine was porter-coloured. Analysis of the urine by one of us (Waldenström) revealed large amounts of uroporphyrin. The diagnosis of acute intermittent porphyria was established—porphyria variegata being unknown at the time.

The patient's condition deteriorated rapidly, and he died in an aspiration pneumonia a few days after the diagnosis was established. At necropsy nothing remarkable was found.

Family C. Case V: 4.

A driving instructor, born in 1930, had good health up to 1962, when he experienced aching pains in the abdomen. As one brother (Case V:2) had died with porphyria he consulted a physician, who, however, did not discover anything remarkable. Routine laboratory tests and PBG in urine were all within normal limits. He was admitted to hospital for four days in October 1963 because of tonsillitis, and treated with penicillin. Dark urine was noted, but no analysis of porphyrins or their precursors was made. The patient had no gastrointestinal symptoms. In August 1966 he was seen by one of us (Haeger-Aronsen) because of backache and intermittent colicky cramps. Several partly pigmented pinhead-sized scars were noted on the back of the hands, particularly in the metacarpophalangeal areas (Fig. 5). The patient reported that during recent years the skin of his hands had become more frail and that he developed chaps and blisters after the slightest trauma. The presence of PV was suspected, and was confirmed by stool analysis, which revealed high excretion of porphyrins (see Table). The patient has never had any symptoms from the central nervous system.

Urine and stool analyses on mother, siblings, and their offspring have shown the mother to be negative, while two sisters (Cases V:1 and V:3), two sons (Cases VI:3 and VI:4), and two nieces (Cases VI:1 and VI:2) are latent. The patient's father died at the age of 42 from pulmonary tuberculosis. His hospital records (Piteå) stated that on three separate occasions his urine was darkish yellow. Porphyrin analysis was not performed.

Discussion

The discovery that the diagnosis porphyria variegata was the correct one in families where the existence of porphyria acuta intermittens earlier had been believed to be confirmed (families B and C) emphasizes the importance of adding faecal

analyses for porphyrins to the examination of urine for the presence of porphyrins and their precursors. Not until the level of faecal porphyrins has been established will it be possible to differentiate between porphyria acuta intermittens and porphyria variegata in the absence of skin symptoms.

FIG. 5.—Hand of Case C, V:4.

From a nosological point of view and also genetically it is of great interest to find out if the two porphyrias with acute abdominal symptoms, one with and one without cutaneous manifestations, are in any way related or are quite independent. We have previously tried in Sweden to discover if cutaneous porphyria might be present in any members of our (approximately) 125 thoroughly studied families with acute intermittent porphyria. So far we have not observed any such cases. It has also become clear that the limited number of cases with the various cutaneous porphyria types have no predilection for the north of Sweden, whereas this is the part of the country

FIG. 6.—Faecal excretion of CP and PP in 18 patients with latent porphyria variegata (PV) and in 12 patients with latent porphyria acuta intermittens (PAI). Inserted vertical and horizontal lines indicate upper limit of normal range of excretion of PP and CP respectively.

where acute intermittent porphyria is very common. A third approach to this problem would be if we could state that the increase in faecal porphyrins characteristic of South African porphyria could be found in members of families with what is believed to be acute intermittent (Swedish) porphyria. So far this has not been possible. Another problem that we have been trying to solve is the following. Could it be that the large number of persons with latent porphyria in Sweden belonging both to PAI and to PV families have about the same biochemical picture, or is there a sharp demarcation line between these groups? We have therefore plotted the data for faecal porphyrins from 18 latent members of our three variegata families in Sweden, together with the data from some persons with latent PAI. This has also been done with urinary ALA and PBG values (Figs. 6 and 7). The graphs clearly show that

FIG. 7.—Urinary excretion of ALA and PBG in 18 patients with latent PV and in 17 patients with latent PAI. Inserted vertical and horizontal lines indicate upper limit of normal range of excretion of PBG and ALA respectively.

the two diseases have different excretory patterns: PV with relatively high faecal porphyrins but mostly normal urinary ALA and PBG, PAI with near normal faecal porphyrins but high ALA and PBG in the urine.

Two different interpretations of the findings regarding these disease pictures have been given. One interpretation, represented among others by Dean, Barnes, and the Malmö group, is that they are fundamentally different. The other, with Watson (1960) as the chief advocate, is that they are "mixed" and that some members for some reason or other also develop skin sensitivity. The most elegant way to prove that the diseases are different would be if they could be shown to be linked and not linked to some well-defined heritable condition. Such studies on our very extensive material are now in progress.

Summary

The three first families with porphyria variegata from Sweden are described. Two of them are descended from Småland, in southern Sweden. In spite of tracing the families back to the beginning and middle of the nineteenth century no relationship has been found with any family in which acute porphyria intermittens has occurred. In all, 24 cases of porphyria variegata are reported—5 manifest and 19 latent.

Supported by a grant to J. Waldenström and B. Haeger-Aronsen from the Swedish Medical Research Council.

Double-blind Experiments on the Effect of a Peanut Extract on the Bleeding Incidence in 92 Haemophiliacs*

M. VERSTRAETE,† M.D.; C. A. J. RUYS,‡ M.D.

Brit. med. J., 1967, 4, 453–456

It is the fate of patients afflicted with a life-long disease to be subjected to therapeutic trials with new drugs or substances, of which the possible impact on the underlying diseases is not always apparent. A classical example is haemophilia; a long list of drugs has stirred a fleeting hope in patients affected with this bleeding disorder when the new therapy coincides with one of their cyclic symptomless periods.

The fortuitous observation by a haemophilic patient that while consuming daily roasted peanuts the tenderness of an acute knee haemarthrosis seemed to subside more rapidly has

focused attention to a possible beneficial factor in peanuts for the treatment of haemophilia (Boudreaux *et al.*, 1960). Largely because of untimely and uncontrolled rumours in the lay press, many haemophiliacs started experimenting on their own with any available source of peanuts—for example, commercial peanut butter, roasted and raw peanuts, or peanut flour.

The discovery of antifibrinolytic properties in peanuts, together with a possibly increased fibrinolytic potential in haemophiliacs (van Creveld *et al.*, 1961), were thought to offer a reasonable basis for further investigation; also because in isolated studies a beneficial effect of peanuts or peanut extracts on the bleeding incidence of haemophilic patients continued to be reported (Brüster, 1961; Bisordi, 1964). Unfortunately these investigations were conducted in a limited number of patients and with a variety of peanut preparations (raw or roasted peanuts, peanut butter, peanut flour, or screw-pressed extracted peanut meal) or peanut extracts (crude peanut oil, hexane-extracted roasted peanuts, or 95% ethanol extract of peanut flour).

* Study organized with the kind co-operation of Belgian and Dutch groups interested in the treatment of haemophilia. Belgium: Louvain (M. Verstraete, J. Vermeylen, and H. Van Isterbeek). Netherlands: Amsterdam (S. van Creveld, I. A. Mochtar, and J. Jonker), Leiden (E. A. Loeliger, A. Hensen, N. Fekkes, and J. J. Velkamp), Breda (C. P. M. Strybos), The Hague (C. H. W. Leeksa), Zevenaar (F. B. M. Verhey).

† Associate Professor of Medicine, University of Louvain, Belgium.

‡ Investigator ACF Amsterdam, Netherlands.

From the Laboratory of Blood Coagulation and Proteolysis, Department of Medicine, University of Louvain, Belgium.

As no double-blind trial on a large group of haemophiliacs had apparently been instituted, it was decided to organize a joint study in Belgium and in the Netherlands, making use of a uniform protocol and a single batch of a given peanut preparation.

Design of the Double-blind Study

Selection of Patients

Only seriously affected haemophiliacs (type A or B) were admitted to this study. In addition to clinical judgement, it was considered that a coagulation time of whole blood over 45 minutes, as assessed with a standardized thromboelastographic method, was a satisfactory criterion, as it would be observed only in haemophiliacs with a very low level of factor VIII or IX. Indeed, it was found that an *r*-value of 45 minutes or more corresponds to 3% factor VIII activity or less.

The different patients were paired according to haemophilia type, age, and social class, so that two groups of patients were obtained in each centre. One group received the placebo product first during 12 weeks, followed by the experimental product during the next 12 weeks (P_1 , E_2); in the second group the order was reversed (E_1 , P_2). The pairing of the patients was made by a person who did not know the treatment group. The purpose of pairing patients according to the criteria given was to take into account the effects of other influences and to avoid a bias due to decreased or increased attention of the patient in his symptoms and the diary kept during the course of the trial.

Evaluation of the Incidence of Bleeding

All patients participating in the collaborative study were requested to visit their physician before and after every sixth week of the trial. At the first visit a questionnaire was explained to the patient which he had to fill in daily (diary). The first list was centred on five frequent bleeding manifestations in haemophilia (ecchymoses, haematomata, haemarthroses, haematuria, and epistaxis); 12 subsidiary questions were aimed to give a rough estimation of duration and importance of a bleeding episode. The patient was also requested to mention each time he sought medical help, was unable to attend class or work, or had to be transfused or admitted to hospital because of bleeding.

The haemophiliacs accepted in this collaborative study were not allowed to take synthetic fibrinolytic inhibitors during the course of the trial—for example, aminocaproic acid or tranexamic acid. If a haemophilic patient had to be admitted to hospital because of bleeding and needed blood transfusion, he interrupted the intake of the experimental product until discharge; during the hospital stay the diary was not filled in. Any other drug—for example, antibiotics, laxatives, expectorants—administered at home had to be recorded daily on the information sheet. The patient was also asked to report any intercurrent disease—for example, common cold, bronchitis.

Haemophiliacs were recommended to refrain from drugs containing salicylates at any time, and particularly during this trial.

At each six-weekly visit the material under trial for the following period was handed to the patient. The physician also inquired about any possible side-effects and the subjective opinion of the patient on the value of the therapy.

Though a new supply of substance was provided every sixth week, it was arranged that placebo or peanut extract was given without interruption for 12 weeks. This rather long period was thought to be essential because peanut extract could require some time before exerting its alleged action on bleeding, which, if present, could last a few weeks after withdrawal of the drug.

At the onset 107 haemophiliacs were included in the trial. In the final study of the results 15 patients had to be excluded for a variety of reasons, such as lack of sustained co-operation, repeated administration of blood or plasma transfusions during the three-month course of the trial, or intervening illness treated with a variety of other drugs.

The final evaluation includes 67 Belgian and 25 Dutch haemophiliacs, four of them being cases of haemophilia B or Christmas disease. The distribution according to age groups was as follows: between 1 and 3 years old, 6 (5 haemophilia A and 1 haemophilia B); over 3 to 14 years, 38 (37 haemophilia A and 1 haemophilia B); and over 14 years, 48 (46 haemophilia A and 2 haemophilia B).

Preparation and Dosage of the Peanut Extract

The peanuts used are of South African origin (common Natal 70/80 hand-picked selected). The peanut extract was prepared and kindly made available free of charge by a pharmaceutical company.¹ One single large batch of experimental product and placebo was used in this trial. Raw peanuts still containing their skin are ground and extracted with hexane until freed of the oily material (Astrup *et al.*, 1962). An alkaline aqueous extract is prepared (pH 6.5), and after centrifugation treated four times with acetone (pH kept at 5.5) and the dry water residue used. Three grammes of raw peanuts yield about 100 mg. of the final powder.

The placebo powder used had the same appearance, smell, and taste as the experimental product.

The daily administered dose of this powder varied according to the age of the patient, but was always given thrice daily (between 1 and 3 years 100 mg. three times; between 3 and 14 years 300 mg. three times; and over 14 years 600 mg. three times). A daily dose of 1,800 mg. of experimental product is the equivalent of about 54 g. of raw pindas.

Results of the Statistical Analysis

Three criteria were used in the final statistical evaluation: the frequency of ecchymoses or of all other bleeding episodes excluding ecchymoses, (epistaxis, haemarthrosis, haematuria, haematoma in muscles, bleeding in mouth and throat) and the duration of absence from school or work because of haemorrhagic incidents. From statistical analysis it appeared that no significant difference in the results for the three criteria mentioned were obtained between the 67 Belgian and 25 Dutch patients. Furthermore, the overall difference in incidence between those who took placebo first and treatment first are not significant. Subsidiary analysis by ages did not reveal a significant difference between the six classes of age groups (1–5 years, 6–10 years, 11–15 years, 16–20 years, 21–30 years, 31 years and over). Therefore as regards nationality, age, class, and trial order the material can be regarded as homogeneous and used as a single group in the final comparison between the effects of the experimental substance and the placebo.

In the left-hand columns of the three sections of the Table are given the differences in incidence for a given criterion between the experimental and placebo period ($E-P$) for the group of 92 haemophiliacs. Negative values of $E-P$ mean a greater bleeding incidence in the placebo periods, positive values of $E-P$ correspond to a greater bleeding incidence in the active treatment period for a given patient. For the three selected criteria the mean of the differences between the treatment periods were close to zero and excludes therefore a significant difference.

Discussion

The initial hypothesis that a genetic block of the metabolic synthesis of factor VIII could have been partially overcome by a factor present in peanuts could not be maintained, as the activity of the coagulation factors VIII and IX was found to be uninfluenced by the consumption of peanuts (Schmutzler, 1961; van Creveld and Mochtar, 1961; Brakman *et al.*, 1962; Verstraete *et al.*, 1962).

Flavanones extracted from peanut skins have a favourable effect on capillary resistance and on the bleeding times of rats (Verstraete *et al.*, 1962). Cepelák (1965) extracted from peanut skins a potent antifibrinolytic substance which promoted haemostasis in haemophilia A and B patients as in other haemorrhagic states. Vasoconstricting compounds were also found in an ethanol extract of defatted peanuts with which a favourable clinical effect was reported (Boudreaux *et al.*, 1960). The same investigators showed that a component of peanuts is being adsorbed into platelets resulting, after viscous metamorphosis, in a potent vasoactive activity which differs from serotonin and cannot be inhibited by atropine. Van Creveld *et al.* (1965), however, obtained a haemostatic effect with a peanut preparation exhibiting antifibrinolytic but no vasoconstrictor activity. More recently it was suggested that the peanut factor might enhance the platelet-plug-stabilization process, and that vasoconstriction was merely incidental to the phenomenon of platelet-plug-induced haemostasis (Frampton *et al.*, 1966).

Astrup *et al.* (1961) found that peanuts and their extracts, with hexane, saline, barbital buffer, or 2 M potassium thiocyanate, exert a powerful protease-inhibiting effect. These results were later confirmed (Schmutzler, 1961; van Creveld and Mochtar, 1961; Verstraete *et al.*, 1962). The antiprotease activity is directed rather against the activation of plasminogen than against formed plasmin. The observation that haemophilic patients may have an increased fibrinolytic activity, as suggested by a short euglobulin lysis time (van Creveld *et al.*, 1961), fits well with the hypothesis of Astrup *et al.* (1961) that an increased fibrinolytic activity which causes no harm in a normal individual could produce bleeding in a patient with an impaired haemostatic balance.

It has further been demonstrated that naturally occurring protease inhibitors, which are proteins or peptides, can pass the intestinal wall and enter the blood stream. After oral adsorption of roasted peanuts a decrease in fibrinolytic activity of euglobulin precipitate (Astrup *et al.*, 1961; van Creveld and Mochtar, 1961; Moers and den Otlander, 1961; Brakman *et al.*, 1962) and an increased inhibitory activity against streptokinase activated human blood (Nilsson, 1960) have been ascribed to the passage of the protease inhibitor through the membranes of the intestinal villi.

In consequence a critical clinical trial with a peanut extract was thought necessary. Our double-blind trial in 92 haemophiliacs did not reveal a statistical difference in the bleeding frequency between the two periods of 12 weeks. These negative

results cannot reasonably be ascribed to an improper selection of the peanut extract used; the hexane extract was prepared from raw peanuts, as it was shown that defatted unroasted peanuts have a twentyfold antifibrinolytic activity compared with roasted peanuts. Moreover, the same type of preparation was reported to be active—that is, induces a decrease of the fibrinolytic activity in the peripheral blood (van Creveld and Mochtar, 1961) and an apparent diminished bleeding incidence in haemophiliacs (Brakman *et al.*, 1962; van Creveld *et al.*, 1965). In the experiments of van Creveld and Mochtar (1961) even the same source of material (Unilever-A.C.F.) but at a lower dose (1.3 times less compared with present trial) was used.

Though it is beyond doubt that peanut extracts, when administered orally, exert an antifibrinolytic effect in the blood, the point is not proved that this inhibitory action is relevant for the prevention of bleeding in haemophiliacs. Some but not all haemophiliacs have a decreased euglobulin lysis time, and a fixed relation between this fibrinolytic activity and the occurrence of bleeding episodes has never been demonstrated (Schmutzler, 1961). Moreover, it was recently shown that peanut extracts almost devoid of antiprotease activity still maintain a haemostatic function probably related to choline or choline derivatives (Frampton *et al.*, 1966; Jackson *et al.*, 1966; Boudreaux, 1967). The choline content of the extract used in this trial was less than 0.22% (Boudreaux, 1967). The hypothesis that the haemostatic effect of ethanol extracts of defatted peanuts were related to their vasoconstricting properties (Boudreaux *et al.*, 1960; Frampton *et al.*, 1966) could not be studied in this trial.

Only patients with severe haemophilia were on purpose selected for this study; it was thought that the clinical evaluation of any drug in haemophilia can hardly be made in mild cases, because such patients have haemorrhagic incidents only after significant haemostatic challenge; the severe haemophiliacs, on the other hand, have incidents of spontaneous haemorrhage.

Most of our patients claimed that their bleeding was less frequent, and that periods of relapse were milder and of shorter duration during the trial; however, these subjective observations were made also during the placebo period, while the patient received the trial substance. Many patients complained on termination of the six months' trial that the bleeding symptoms became worse. One possible explanation is that hope and better medical attention of the haemophilic patients induced by the six-weekly visits to their physicians could be responsible for this bias.

Our results are not in keeping with the experiments of Brüster (1961, 1962), who observed after the oral intake of 15 g. of the hexane extract of peanuts a decrease in the coagulation time, an improvement in the results with the thromboplastin generation test and prothrombin consumption, and a definite haemostatic effect in five haemophiliacs A and seven haemophiliacs B.

With the peanut preparation evaluated in the present double-blind trial on 92 haemophiliacs no favourable effect on bleeding could be observed. Based on these findings we would propose to refrain from recommending peanuts or their extracts as a haemostatic agent to haemophilic patients until definite proof of the beneficial effect of a given peanut preparation to the control of haemophilic bleeding is presented.

Summary

The haemostatic value of an aqueous extract of raw ground and hexane-defatted peanut kernels was evaluated in 92 severely affected haemophilic patients during a six-months double-blind trial. With the criteria selected, no statistical proved benefit on the bleeding incidence could be demonstrated during the "active" treatment.

Effect of Vagotomy on Gastric Acid Secretion Stimulated by Pentagastrin and Histamine

R. A. PAYNE,* M.S., F.R.C.S.; ALAN G. COX,† M.D., F.R.C.S.ED.; JOHN SPENCER,‡ M.B., B.S., F.R.C.S.

Brit. med. J., 1967, 4, 456-457

The study of human gastric acid secretion has been hindered by lack of a readily available agent which has the properties of gastrin and which can be administered to man with safety. Hog antral mucosa has provided a source of gastrin for animal experimentation, but until isolated in a pure form by Gregory and Tracy (1964) gastrin has not been available for use in man. The production of pure gastrin on a commercial scale has not proved practicable. However, since the introduction of a synthetic substance known as pentagastrin (Peptavlon, I.C.I.) the physiological properties of gastrin can be studied. This is a pentapeptide with a terminal tetrapeptide which appears to be the physiologically active constituent of gastrin (Tracy and Gregory, 1964).

The present investigation was undertaken to compare the effect of vagotomy (with pyloroplasty) on the maximal gastric responses to stimulation by histamine and by pentagastrin. Histamine has been widely used to study acid secretion, but it may now be superseded by pentagastrin. It is therefore important to determine if the results of investigations with pentagastrin can be compared with those of previous work with histamine.

Method of Study

Fifteen patients with uncomplicated chronic duodenal ulcer were studied before and after total vagotomy with pyloroplasty. Before operation the maximal acid responses to histamine and to pentagastrin were measured on two separate days. Seven to 10 days after operation an insulin test was performed to confirm the completeness of vagotomy, and the two tests with

histamine and pentagastrin were then repeated on successive days.

All secretory tests were carried out in the morning after an overnight fast. Before operation a 16 French gauge nasogastric tube was passed into the most dependent part of the stomach under x-ray control. In the postoperative tests use was made of a double-lumen feeding gastrostomy tube for collection of the gastric secretions. The tube was placed at operation with one limb in the dependent part of the stomach and the other in the duodenum (Burns and Menzies, 1966). In all tests gastric juice was aspirated continuously by an electric pump at a subatmospheric pressure of 5 cm. Hg, and the patency of the tube was checked at frequent intervals throughout each test. The aspirations were collected in 15-minute samples and their total acid content in mEq was measured by titration with 0.1N NaOH to the phenol red end-point (pH 6.8-8.4).

In each test two 15-minute specimens of basal secretion were collected after aspiration of the fasting juice. The tests then continued as follows:

Maximal Histamine Response.—Histamine acid phosphate was infused intravenously at a rate of 40 µg./kg./hour (Lawrie *et al.*, 1964) for 120 minutes. The maximal response was taken as the sum of the four consecutive samples giving the highest total.

Maximal Pentagastrin Response.—Pentagastrin was infused intravenously at a rate of 6 µg./kg./hour for 90 minutes, which is sufficient to give a steady level of secretion (Multicentre Pilot Study, 1967). The maximal response was calculated as for the histamine test.

Insulin Test.—Soluble insulin, 0.25 unit/mg., was injected in a single intravenous dose and completeness of vagotomy was accepted if the concentration of acid in the next two hours failed to rise by more than 20 mEq/litre above the basal concentration.

Results

Table I shows the maximal response to histamine and pentagastrin before and after vagotomy in each patient. All 15 patients showed a substantially reduced response to both

agents after vagotomy. The reduction in the response due to vagotomy is usually expressed as a percentage of the preoperative value, and the result of this calculation is shown for each patient in Table II. The mean reduction in the histamine response (66.4%) does not differ significantly from the mean reduction in the pentagastrin response (61.5%). The correlation between the two reductions is shown in the Chart and is statistically significant ($P < 0.001$).

Some of our results with pentagastrin formed part of an investigation into the effects of vagotomy on gastric acid secretion elicited by pentagastrin (Multicentre Study, 1967).

Correlation of percentage reduction after vagotomy of Pentagastrin- and histamine-stimulated maximal gastric acid secretion. The correlation coefficient is $+0.968$ ($P < 0.001$). The equation for the regression line is $y = 0.968x \pm 2.37$.

Discussion

This investigation shows that vagotomy reduces the maximal gastric acid secretory response to pentagastrin and to histamine by similar proportions. A similar finding has been reported by Jepson and Johnston (1967) in a study of the effects of vagotomy on Histalog- (ametazone hydrochloride) and pentagastrin-stimulated acid secretion. Their observations contrast with the results of a previous study from this centre (Barabas *et al.*, 1966) in which a hog antral mucosal extract of gastrin (Leo) was used instead of pentagastrin. In that study the reduction in acid secretion after vagotomy was 60% with histamine and only 33% with the mucosal extract. A similar observation has been made by Weir *et al.* (1966). Bank *et al.* (1967), in a study of patients after vagotomy, state that the pentagastrin response is greater than the histamine response. The implication that the pentagastrin response is reduced less than the histamine response was not substantiated, since no tests with pentagastrin were carried out before vagotomy. In a Multicentre Study (1967) of the effects of vagotomy on the maximal acid secretory response to pentagastrin a mean reduction of 62% was found after vagotomy, but measurements of histamine-stimulated acid secretion were not made.

Comparison of the results of our earlier study (Barabas *et al.*, 1966) and the present one suggests a difference between the properties of the synthetic pentapeptide and the mucosal extract. This is supported by the work of Neely (1967), who made a direct comparison of the effect of these two agents on alimentary motility and found a difference in the response of the small intestine. Our present results with pentagastrin conform more closely with the observation of Welbourn and Burns (1964) that vagotomy in man reduced by 67% the acid output to endogenous gastrin after perfusion of the stomach with a meal extract.

Unlike histamine, pentagastrin has minimal side-effects and seems likely to supersede it in the measurement of gastric acid secretion. Our present study allows the practical conclusion that the results with pentagastrin are closely comparable to those following histamine stimulation both before and after vagotomy.

Summary

Maximal gastric acid secretion in response to intravenous infusions of pentagastrin (Peptavlon) and histamine has been measured before and after complete surgical vagotomy in 15 patients with chronic duodenal ulcer. After vagotomy the response to both stimulants was reduced by similar proportions.

We wish to express our appreciation to the following: Professor R. B. Welbourn for advice and encouragement; Staff Nurses Alexander, Sherman, and Pope and Mrs. Vedast for help with the tests; the N.E. Metropolitan Regional Hospital Board for a research grant (R. A. P.); and I.C.I. for supplies of Peptavlon and the salary of a technician (A. G. C.).

Brit. med. J., 1967, 4, 458-460.

Laboratories interested in blood group serology need to preserve a reference panel of red cells of known antigenic structure. For the sake of continuous availability, especially of the rarer types, it is often desirable that the cells should be stored for long periods of time at sub-zero temperatures, a state which can be achieved without gross lysis only by the use of special techniques. For some years past we have been evaluating the quality of preservation of human red cells stored in liquid nitrogen (-196°C) after rapid freezing of droplets of a whole-blood/sucrose mixture; the present paper records the behaviour of a panel of such cells, selected on account of their diverse grouping properties, and tested after storage for five years.

The methods employed were as previously reported (Huntsman, *et al.*, 1962).

Results

Recovery of Intact Cells.—The average recovery in seven samples was 89.4% (range 87-94%); changes in the average recovery over the five-year period are shown in Table I.

Antigen Strength.—The blood groups of the panel of cells are listed in Table II, and the titration scores of these cells after varying periods of storage are shown in Table III. The results on fresh samples from four of the original donors, tested in parallel with the five-year stored samples, are also included in Table III.

TABLE I—Average Recovery of Intact Cells When Thawed After Storage for Various Periods of Time

Discussion

Strumia *et al.* (1960) reported a 90% recovery of red cells after storage for two years at -93°C . and Doebbler *et al.* (1965) found no significant change in red cell recovery rates after two and a half years at -170°C . The recovery of a high proportion of intact cells after five years' storage at -196°C . (Table I) confirms that this technique is capable of preserving red cells intact for long periods. The increase in recovery at one year was due to the use of 1% (rather than isotonic) saline for thawing; thereafter the proportion of cells recovered intact appears to drop by approximately 1% per annum.

Earlier work had suggested that the antigenic strength of frozen red cells would show little deterioration during storage. The panel of cells reported in this paper retained their antigenic strength after three years in liquid nitrogen (Huntsman *et al.*, 1964). Strumia *et al.* (1962) showed that a small panel of cells grouped satisfactorily after five months at -93°C . One specimen after three years' storage was equivalent to fresh cells. Bronson and McGinniss (1962) reported good preservation of antigenic properties after the storage of two samples for six months in liquid nitrogen. Gibbs *et al.* (1962) showed that the antigens of the ABO systems were preserved after two and a half years in liquid nitrogen.

As previously observed (Huntsman *et al.*, 1964) saline suspensions of thawed cells showed progressive lysis during further storage over a period of hours or days at 4°C ., but this feature was no more pronounced in the five-year specimens than in those frozen for a shorter period. All cell samples after repeated washing in isotonic saline showed no further haemolysis before grouping tests, some of which were carried out as long as 48 hours after thawing.

The quality of the antigen strength of red cells after five years of frozen storage is reflected by the titration scores shown in Table III, and, with few exceptions of doubtful significance, the results are similar to those obtained with the original fresh material. After this period of trial it is fair to say that cells stored by the method described compare favourably with cells frozen in high concentrations of glycerol and stored under the best conditions at -80°C . or below. Storage of glycerolized cells at -20°C . gives inferior results, and indeed few of the cells would be expected to survive for five years under such conditions.

In order to detect enzyme deterioration in the stored red cells we have previously relied on assays repeated sequentially over a number of years. As a result of such tests it appeared that the concentrations of two of the four enzymes (aldolase and aspartate aminotransferase) had fallen during storage for two years. However, it is difficult to stabilize enzyme assay systems so as to yield strictly comparable results over long periods of time, and adequate preparations for quality control of these assay procedures do not exist. The possibility was therefore considered that the observations might be due to technical variation rather than to changes in the stored enzymes (Huntsman *et al.*, 1965). Samples after five years' storage were com-

pared with freshly drawn specimens from the original donors, related samples being assayed simultaneously in each case. During the period of storage whenever specimens were temporarily removed from the liquid nitrogen refrigerator care was taken that the frozen blood remained at liquid nitrogen temperature. This was achieved by ensuring that the boxes containing the blood were filled with liquid nitrogen the moment they were removed from the refrigerator. The results of these tests are given in Table IV. The present evidence,

though inconclusive, suggests a reasonable degree of stability of these four enzymes during storage at -196°C .

Summary

Tests after five years' storage of human blood in liquid nitrogen (-196°C) after rapid freezing shows the method to be very suitable for preservation of cells for blood group

Haemorrhagic Necrosis of the Intestine

J. S. MCKINNELL,* M.B., CH.B., D.PATH., F.C.PATH.; M. S. KEARNEY,† M.B., CH.B.

Brit. med. J., 1967, 4, 460-463

The fact that necrosis of the bowel can occur in the absence of demonstrable occlusion of the mesenteric vessels has long been recognized. Kleckner, Bagen, and Baggenstoss (1953) recognized that enterocolitis occurred in heart disease, but Wilson and Qualheim (1954) seem to have been the first to define a specific syndrome occurring mainly in elderly subjects suffering from heart disease and characterized by patchy haemorrhagic necrosis of the intestinal mucosa unrelated to the distribution of the mesenteric arteries. These authors observed eight cases of acute haemorrhagic enterocolitis in one and a half years and discovered 12 similar cases in a survey of the hospital necropsy records between 1947 and 1953. Subsequently a number of American authors have described further cases of the same type: Ming and Levitan (1960) encountered 11 in three years among 698 necropsies; Glotzer and Shaw (1959) collected nine in a period of 10 years; Grosh, Mann, and O'Donnell (1965) described 10 cases seen in three years; in a study of hospital records over a 12-year period Berger and Byrne (1961) found 23 cases of massive bowel infarction in the absence of mesenteric artery or vein occlusion, though at necropsy the majority showed infarction in the distribution of the superior mesenteric artery and only a minority showed involvement of multiple segments at random sites; Fogarty and Fletcher (1966) studied 18 patients during five years; Drucker, Davis, Holden, and Reagan (1964) observed seven patients within two years. The last-mentioned authors discuss the pathogenesis. In a report from Australia, McGovern and Goulston (1965) recorded 33 cases in a 14-year period.

No series of exactly comparable cases seems to have been reported from this country. During the five months July to November 1964 we encountered 13 cases among fewer than 200 necropsies. Previous to this period such cases were very rare in the experience of one of us (J. S. McK.), and subsequently in the same hospital there have been only two similar cases among over 1,000 necropsies. The only unusual feature of the five months in question was that they were unusually dry; the rainfall in these five months totalled 3.5 in. (8.9 cm.), as compared with an average of 7 in. (17.8 cm.) for the same five months in the years 1947 to 1961. No other late summer and autumn since 1947 had been so dry.

Reports of two representative cases are given.

Case 1

The patient, a man aged 85, was admitted to hospital with a history of abdominal pain for some days, becoming more severe in the previous 24 hours.

* Consultant Pathologist, Selly Oak Hospital, Birmingham 29.
† Surgeon Lieutenant, R.N.; Late Registrar in Pathology, Selly Oak Hospital, Birmingham 29.

On examination the transverse colon was distended and showed visible peristalsis. He was dehydrated. The rectum contained hard faeces. Levels of serum electrolytes were: sodium 134 mEq/l., potassium 3.5 mEq/l., chloride 86 mEq/l., and bicarbonate 29 mEq/l. The blood urea was 76 mg./100 ml. A provisional diagnosis of carcinoma of the colon was made. One litre of dextrose saline and one litre of Dacron solution were infused in 12 hours, but the patient collapsed unexpectedly and died 48 hours after admission.

At necropsy the heart was of normal size. The myocardium was flabby. The valves were normal. The coronary arteries were moderately dilated and there was diffuse thickening of their walls, but there were no atheromatous plaques and no restriction of their lumina. The lungs were oedematous and congested. The liver was rather small and its surface was mottled, due to irregular patches of congestion. The gastric mucosa and the mucosa of the whole length of the small intestine were acutely congested, and gas bubbles were observed under the mucosa of the duodenum. There were small haemorrhages in the mesentery of the jejunum. The mucosa of the caecum was severely haemorrhagic and much thickened. In the transverse colon there were two segments in which the mucosa was greenish and the wall of the bowel thinned owing to dilatation. The mucosa of the pelvic colon was thickened and haemorrhagic, like that of the caecum. The aorta was well preserved for the age of the subject, and the superior and inferior mesenteric arteries and veins were patent. The kidneys showed some loss of cortical substance with coarse granularity of the subcapsular surface, suggestive of scarring due to senile arteriosclerosis. There was moderate dilatation of both renal pelves, the bladder was moderately dilated and trabeculated, and the prostate was enlarged.

On histological examination the more severely affected areas of the small intestine, the caecum, and the pelvic colon all showed essentially similar changes, consisting of haemorrhage into the mucosa and severe congestion of the submucosa with thrombosis

Fig. 1.—Case 1. Superficial necrosis of the mucosa with haemorrhage in the deeper zone. Severe congestion of the vessels of the submucosa with some oedema.

of a few small veins (see Fig. 1). Inflammatory cellular exudate was slight and diffuse in all coats. Large numbers of thick Gram-positive rods were present on the surface of the haemorrhagic mucosa. There were also large numbers of organisms in the mucosa and submucosa, and to a lesser extent in the other coats, but these were mainly Gram-negative rods. In the transverse colon affected areas showed thinning and necrosis of the mucosa with thinning of the wall of the colon, presumably due to dilatation of its lumen. Here organisms were less numerous, there being a few Gram-negative rods in the mucosa and submucosa. Culture of the small intestine revealed *Clostridium welchii* and *Escherichia coli*.

Case 4

This man, aged 75, had been treated by his family doctor for several years for congestive heart failure. He had been well maintained on diuretics and digoxin. On the day of admission he became jaundiced and complained of vague abdominal pain.

On examination he was obviously very ill, jaundiced, dyspnoeic, and cyanosed, with gross ankle oedema. He was pulseless and the heart sounds were inaudible. Shortly afterwards he had a massive rectal haemorrhage of fresh blood and died 33 hours after admission.

At necropsy there were bilateral pleural adhesions, and the lungs were oedematous and congested. Both ventricles of the heart were hypertrophied and dilated, and there was some dilatation of the atria. The myocardium was soft and flabby. The valves were normal and the coronary arteries showed only minimal atheroma. The heart weighed 505 g. There were several small acute ulcers of the gastric mucosa and petechial haemorrhages in patches at the cardiac end. From the duodenum to the rectum there was intense congestion, most severe in the duodenum, terminal ileum, and colon. The mucosa of the terminal ileum was haemorrhagic and thickened, with small irregular ulcers between thickened mucosal folds. The caecum was less severely congested and haemorrhagic, but there were a few ragged erosions and rounded ulcers 2 to 6 mm. in diameter. The mucosa of the anterior wall of the ascending colon was ulcerated in a strip 2 cm. wide. The distal half of the transverse colon and the descending colon showed the most severe changes. The mucosa was almost black, due to massive haemorrhage, and much thickened; areas up to 1.5 cm. in diameter were denuded of mucosa. There was no pseudomembrane. There were some calcified mesenteric lymph nodes. The mesenteric arteries and veins were patent and the aorta was only moderately atheromatous. Liver and kidneys showed cloudy swelling but were otherwise normal. The other organs showed nothing remarkable.

Histological examination showed much mucosal haemorrhage and a variable amount of necrosis and ulceration in the affected zones at all levels in the intestine. There was submucosal oedema and congestion with "thrombi" consisting mainly of aggregated red cells in small veins. Many Gram-negative rods and a few Gram-positive rods were found in the mucosa.

Clinical Picture

Table I summarizes the clinical features. Of the 13 patients, 12 were 64 years of age or older; the exception was a 45-year-old mentally subnormal woman who refused food and required tube-feeding. There were seven women and six men. Abdominal pain was a feature in seven cases. Vomiting was recorded in six patients and haematemesis in one of these. Diarrhoea occurred in four, and rectal bleeding in six. There was no abdominal pain in five cases. Terminal collapse was observed in 10 cases and severe peripheral cyanosis was recorded in three.

In 10 cases congestive cardiac failure had been present at some time, but only six of these were in failure at the time of admission to hospital. In two cases there was a recent myocardial infarct. In three cases there was no evidence of any heart disease. In two cases there was thrombocytopenia; one of these was uraemic owing to urinary tract infection. One case was on anticoagulant therapy with phenindione. In all cases the blood urea was above normal, but in the only three in which it was estimated on more than one occasion there was evidence of a steep rise between the onset of abdominal symptoms and death. In three cases significant nitrogen reten-

* Post-mortem value

tion could have been the result of primary renal disease, there being evidence of pyelonephritis in two and carcinoma of the prostate in one. In three cases plasma potassium was low or rather low—3.5, 4, and 4.1 mEq/l.—while in one case it was raised to 5.6 mEq/l.

Table II summarizes the treatment which 10 of these patients had received before the terminal illness. Case 1 had no previous significant illness, and in Cases 7 and 10 our information is incomplete. One patient was known to have taken an overdose of digitalis in the period immediately before the onset of abdominal symptoms. The antibiotics had been given at varying intervals before the final catastrophe and do not seem to have played a significant part.

TABLE II.—Summary of Drugs Which Had Been Administered Before the Onset of Symptoms

Pathology

A characteristic feature was the patchy distribution of the changes, which consisted mainly of congestion of the mucosa, varying in degree from slight to very severe, accompanied by intramucosal haemorrhage which rendered the bowel wall thick and turgid, the mucosal surface being dark brown and slightly rough to the touch in those areas. In a few, as in Case 1, there were areas in which the wall of the colon was thinned, the mucosal surface being greenish and smooth; this phenomenon seemed to be secondary to dilatation of the colon proximal to haemorrhagic necrosis of the mucosa of the distal colon. In some cases the wall of the small intestine was diffusely plum-coloured and there was a little blood-stained fluid in the peritoneal cavity. In some such areas there were bubbles of gas in the submucosa. Fig. 2 gives a diagrammatic representation of the extent of involvement in the individual cases.

FIG. 2.—The solid black areas indicate haemorrhagic necrosis of the mucosa. The stippled areas indicate severe congestion with petechial haemorrhages.

Microscopically the characteristic features were haemorrhage into the mucosa with superficial necrosis. In the submucosa the veins were congested, some giving an impression of thrombosis, probably due to aggregation of red cells rather than to actual clotting, there being no obvious fibrin or platelet thrombi. In some cases there was oedema of the submucosa. Cellular inflammatory exudate was mainly slight, except in the few cases where there were areas of ulceration. The muscular and serosal coats were not greatly affected in most cases. In the dilated colon, where the mucosa was green and smooth, macroscopic examination showed necrosis of the thinned mucosa with almost no reaction.

Bacteriological Examination

Culture of the affected intestine, the small intestine being sampled when it was involved, gave in all cases a growth of *Cl. welchii*. All strains were tested for heat resistance, with negative results. This observation is of doubtful value, however, as the test was performed on cultures of the organism in Robertson's meat medium and not on the tissue itself: in these circumstances the spores may have germinated before being subjected to heat. The three strains which were tested were shown by toxin analysis to be of type A. Of the eight cases in which the other organisms present were identified, *E. coli* was recognized in five, *Streptococcus faecalis* in six, a *Klebsiella* in two, and *Pseudomonas pyocyanea* and *Sarcina* in one each. In three cases intestinal viruses were looked for, with negative results.

Discussion

Haemorrhagic necrosis of the bowel mucosa of patchy distribution occurring in elderly cardiac invalids has its own characteristics, but it shares some features with other types of acute non-occlusive intestinal necrosis. Among others, Dawson-Edwards and Morrissey (1955) and Kay, Richards, and Watson (1958) described cases of acute necrotizing colitis characterized by disseminated areas of congestion, necrosis, and ulceration of the mucosa. Not all of these cases could properly be described as "pseudomembranous" colitis, but they lacked the massive haemorrhage seen in the present series. These cases were predominantly postoperative and usually followed partial gastrectomy, though two cases of the series of Kay *et al.* were preceded by myocardial infarction. Undue operative shock was not a feature of either series and antibiotic administration was not thought to be an important factor. *Cl. welchii* was isolated in eight of the 14 cases described by Kay *et al.*, while in the other cases bacteriological examination was incomplete or omitted. Staphylococci were isolated in four cases. It is of interest that Howie, Duncan, and Mackie (1953) have demonstrated growth of *Cl. welchii* in the stomach after partial gastrectomy.

A number of types of necrotizing intestinal lesions have been described in which the causative agent seems to have been *Cl. welchii*. Cases of enteritis necroticans (*Darmbrand*) thought to have been due to ingestion of *Cl. welchii* from tinned meats were seen in Northern Germany in the summer of 1946 and again in 1947 (Jeckeln, 1947, 1948). The jejunum was most severely involved, but the ileum and the colon were occasionally affected. The disease was most severe in elderly patients and in young children, but occurred at all ages. Malnutrition may well have been a contributing factor. In those who survived the acute stage there was a tendency to perforation and stricture formation. A similar condition has been described in Papuan natives, caused by the consumption of poorly preserved pork in large quantities at times of festival (Murrell and Roth, 1963). Heat-resistant strains of *Cl. welchii* were incriminated in these outbreaks. The German strain is said to have been of type F (Zeissler and Rassfeld-Sternberg, 1949), while that from Papua was probably of type C.

Gas gangrene of the intestine has been described as a complication of leukaemia (Amromin and Solomon, 1962) and is not rare after haemorrhage from a peptic ulcer. Killingback and Lloyd Williams (1961) described six cases of necrotizing colitis of acute onset in previously well elderly subjects. Histological examination suggested the possibility of a clostridial cause. Resection of the affected colon was life-saving in three cases. Tate, Thompson, and Willis (1965) isolated a heat-resistant strain of *Cl. welchii* type A from a similar case.

The fact that we were able to grow *Cl. welchii* from all our cases may have been significant. Though *Cl. welchii* is a common inhabitant of the colon it can in our experience be isolated from the bowel in only about 70% of necropsies. The significance of heat resistance as a characteristic of food-poisoning strains of *Cl. welchii* has probably been exaggerated in the past, and there is some evidence to suggest that non-heat-resistant strains may also be capable of producing food poisoning (Taylor and Coetzee, 1966). The same consideration may well apply to the production of necrotizing enterocolitis in susceptible subjects, but even if *Cl. welchii* is a factor in precipitating this condition there are obviously important predisposing causes.

Among others, Marston (1962, 1964) stressed the role of ischaemia in the production of necrosis of the intestine. He also drew attention to the condition of haemorrhagic necrosis of the intestine occurring in dogs subjected to hypovolaemic shock. While we agree that anoxia is an important factor, the mesenteric arteries in our cases were not affected by atheroma to any significant degree, except in one case in which the inferior mesenteric artery was completely occluded and a plaque of atheroma was present in the main trunk of the superior mesenteric; and there was nothing in the histological sections to suggest anatomical occlusion of the small arteries, though in some cases apparent thickening of the walls of the small arteries relative to the area of the cross-section of their lumina suggested the possibility of spasm. Except for the two cases of myocardial infarction there was no reason to suspect shock as a primary factor. However, Corday, Irving, Gold, Bernstein, and Skelton (1962) have pointed out that mesenteric arteriolar spasm may result from cardiac arrhythmias and congestive heart failure as well as from hypotension and from the administration of vasopressor drugs.

Dehydration from diuretic therapy may aggravate both the arteriospasm and the congestion, favouring aggregation of red cells in the submucosal venules. Dehydration was perhaps a major factor in the youngest patient, who had been refusing food and drink. Prolonged treatment of congestive cardiac failure with thiazide diuretics tends to deplete the cells of potassium, even though serum potassium may remain normal. Though the effect of electrolyte imbalance on the intestine is complex, loss of cellular potassium tends to lower intestinal motility and may well favour proliferation of organisms in the small bowel.

The role of digitalis has been emphasized by Gazes, Holmes, Moseley, and Pratt-Thomas (1961); all their 10 patients seen in a period of 10 years had received large doses of digitalis and several were suffering from digitalis toxicity. They reviewed the evidence in the literature that digitalis causes pooling of blood in splanchnic vessels, possibly by causing spasm of hepatic veins or of portal venules. They also pointed out that a maintenance dose of digitalis may become toxic when potassium is lost from the body.

Treatment

The treatment of haemorrhagic enterocolitis is unsatisfactory. Laparotomy may have to be performed to rule out mesenteric vascular occlusion or necrotizing colitis, but resection of bowel should be avoided if possible. The administration of dextran of low molecular weights may improve the circulation in the intestinal wall, not so much by expanding the plasma volume

as by favouring the disaggregation of red cells. Potassium depletion should be corrected. Vasopressors, especially angiotensin amide, should be avoided as being likely to increase vascular spasm. Judicious dosage of metaraminol or nor-adrenaline acid tartrate (levarterenol) may be less objectionable in the presence of septic shock (Smulyan, Cuddy, and Eich, 1964), but present opinion on the treatment of shock favours drugs which increase peripheral blood flow (*Brit. med. J.*, 1966). For this purpose either the alpha-adrenergic antagonist phenoxybenzamine or the quicker-acting beta-adrenergic receptor stimulator isoprenaline (du Toit, du Plessis, Dommissie, Rorke, Theron, and de Villiers, 1966) or orciprenaline, which is recommended by Shanks, Brick, Hutchison, and Roddie (1967) as being more easily obtainable, may be given. When using any of these drugs appropriate infusions should be administered to expand the blood volume to match the increased vascular bed. If we are correct in thinking that splanchnic vasoconstriction is an important cause of haemorrhagic enterocolitis this treatment should be instituted at the earliest possible moment, preferably before the development of the terminal collapse.

It would seem reasonable to administer anti-gas-gangrene serum and massive doses of antibiotics directed both against *Cl. welchii* and against the secondary invaders which may colonize the haemorrhagic and necrotic mucosa.

Summary

The clinical and pathological features of 13 cases of acute haemorrhagic enterocolitis which were seen in one hospital during an unusually dry spell in the summer and autumn of 1964 are described. It is suggested that, while the basic cause is probably reduction of the blood flow through the wall of the intestine, this is usually due to functional factors associated with heart failure and its treatment and not to anatomical lesions in the splanchnic blood vessels. It is also suggested that usually harmless organisms ingested in unusually large numbers owing to climatic conditions, and possibly proliferating in the intestinal contents owing to stasis, may have precipitated this haemorrhagic necrosis of the mucosa.

Preliminary Communications

Prevention of Delayed Traumatic Facial Palsy

Brit. med. J., 1967, 4, 464-465

Taverner *et al.* (1966) showed that treatment with intramuscular A.C.T.H. gel increased the recovery rate from Bell's palsy and reduced the incidence of denervation. They claimed that even better results would be obtained if all patients were treated within 24 hours of the onset of paralysis. It is possible that the mechanism of delayed traumatic facial weakness is similar to that of Bell's palsy and that in both conditions there is an inflammatory reaction in or around, or a swelling of the facial nerve in its canal, and that this leads to ischaemia and in some cases to denervation. If this is so, and if one could identify those patients particularly liable to develop this complication of head injury, it might be expected that prophylactic treatment with A.C.T.H. would be effective.

The results we have obtained so far are sufficiently suggestive of a protective value of A.C.T.H. against late traumatic facial weakness that we feel justified in publishing this preliminary communication—particularly since, with Taverner *et al.*, we have found the treatment itself to be harmless, provided a correct dosage is observed.

SELECTION OF PATIENTS

In cases of head injury, damage to the facial nerve in its canal is nearly always associated with a fractured petrous bone, though it may sometimes be difficult, even with specially projected views, to demonstrate radiologically the fracture and its precise relation to the facial canal. A common clinical sign of this type of fracture is bleeding from the ear on the same side. In a series of 2,712 consecutive and unselected cases of head injury admitted to the Radcliffe Infirmary, Oxford, some degree of facial nerve involvement was detected in approximately 50% of patients showing unequivocal radiological evidence of a fractured petrous bone whether or not this was accompanied by a bleeding ear (Potter, 1964).

Two varieties of facial weakness are usually recognized: *immediate*, where the nerve has been directly concussed, contused, or lacerated at the moment of injury; and *delayed*, where the weakness results from some reaction occurring after an interval, usually during the first week or occasionally even later. In addition, a third, or *mixed*, group of cases can be recognized, where there has been an immediate weakness, which may then either recover and be followed by delayed weakness or progress later to a more severe weakness or complete paralysis (Potter, 1964). It is not our policy to operate on patients in the first group, and the present paper is concerned with *delayed facial weakness only*. The prognosis in this variety is normally good, but denervation and perverted reinnervation may occur and result in some permanent disfigurement. Prevention of the complication should therefore be attempted if a simple and safe method is available, and this appears to be provided by A.C.T.H.

In choosing patients for prophylactic treatment we felt it desirable that criteria should be used which could be readily recognized in casualty departments without the need to employ sophisticated techniques of investigation. It was also necessary that we should be able to discover, from an untreated control

group, the expected incidence of facial weakness in the series to be treated.

During the past year we therefore selected all patients who had a bleeding ear and who were shown also to have radiological evidence of a petrous temporal fracture on the same side. Those with blood behind an intact drum were not included. In an earlier series of 5,000 consecutive and unselected cases of head injury admitted to this unit between 5 January 1962 and 9 May 1965 we found that there had been 70 patients with the same combination of a fractured petrous bone and a bleeding ear and that 27 of these had shown some degree of delayed facial weakness—an expected incidence for this complication, therefore, of 38.5%.

RESULTS

In the past year there have been 16 patients showing the combination of a fractured petrous bone and bleeding ear, and all have received prophylactic A.C.T.H. soon after the injury. Without treatment we should have expected six of these patients to develop some delayed facial weakness; but only two did so. One developed rapidly a complete facial palsy on the second day after injury; denervation ensued despite treatment, and there has been no recovery during the month following the injury. In the second case there was only slight and transient facial weakness lasting for some 10 hours on the second day after injury. The ages of the 16 patients ranged from 2 to 77.

We have the impression—but it is no more than a clinical impression—that these patients receiving A.C.T.H. have recovered unusually smoothly from the other effects of their head injuries.

METHOD

Corticotrophin (A.C.T.H.) gelatin injection B.P. was given daily by intramuscular injection for eight days. Since, in the great majority of cases, delayed traumatic facial weakness appears during the week following injury (Turner, 1944; Potter, 1964) and because our object was prophylaxis, we did not feel it necessary to employ the full 10-day therapeutic course adopted by Taverner *et al.* for patients with Bell's palsy, except in the case of a single patient who developed the complete paralysis between the second and third doses.

The first injection was given within a few hours of the injury. The dosage was as follows: 80 units daily for three days, 60 units on the fourth day, 40 units on the fifth day, 20 units on the sixth day, and 10 units on both the seventh and eighth days. For children the dosage was reduced according to weight and age, but this reduction was apparently insufficient in a 3½-year-old who showed marked oedema of the lower abdominal wall and genitalia for five days at the end of his course of treatment.

Though one might suspect that the plasma cortisol level is relevant to this problem, we know of no certain evidence yet that this is so, and Taverner (1954) had already found cortisone ineffective in the treatment of Bell's palsy. Nevertheless, after the first dose we gave the A.C.T.H. in the afternoons, because it is known that the plasma cortisol is normally at a relatively low level at that time—as also is the level of A.C.T.H. (Ney *et al.*, 1963). (If, indeed, a high plasma cortisol level contributes to the protection of a patient from delayed traumatic facial weakness we would expect this complication to occur less often in the more severely injured patients. This possibility is at present under investigation.)

SUMMARY

Sixteen patients were given prophylactic A.C.T.H. after they had sustained head injuries. Each had shown radiological evidence of a fractured petrous bone and had had bleeding from the ipsilateral ear.

The expected incidence in an untreated group of the same size would have been six patients showing delayed facial weakness.

Only two patients developed delayed facial weakness. In both this occurred on the second day. In one it was mild and lasted only 10 hours; in the other it was complete and denervation occurred despite treatment.

It seems that A.C.T.H. offers some protection against this complication of head injury.

We are grateful to Dr. T. D. A. Hockaday and Mr. George Higgins for their expert help and advice.

Medical Memoranda**Sarcoid Myopathy**

Brit. med. J., 1967, 4, 465-466

Only 12 cases (Hinterbuchner and Hinterbuchner, 1964) have been found in the literature where sarcoidosis presented as a pure myopathy with no evidence of other systemic involvement. I present another case which has responded dramatically to corticosteroid therapy.

CASE HISTORY

A 55-year-old Englishwoman presented in March 1966 with a three-week history of calf stiffness alleviated by exercise. She had no other symptoms, was on no drugs, and had no relevant family or social history.

In April she was admitted to hospital, and examination showed severe weakness in her legs, more so on the left, with slight thigh wasting. Weakness was also present in the elbows and wrists, but without wasting. The muscles were non-tender and felt normal. Her gait was stiff and wide-based, and she tired easily. No other significant abnormality was found and no definitive diagnosis made. Physiotherapy produced some improvement, and she was discharged after one month. By August wasting and weakness had developed in all proximal limb muscles. Walking was difficult without support, resulting in several falls.

She was readmitted to hospital in January 1967 with severe weakness in her hands, hardly able to walk even with support, and unable to sit up unaided or do her hair. She had an occasional dry cough but no other complaints. Examination showed obvious muscle wasting of all the limbs, whose tone was slightly reduced. The muscles felt rubbery but were not tender, fasciculating, or showing involuntary movements. Movement was full, but with severe generalized weakness, including the sternomastoids and face. The other systems showed no abnormality.

Investigations.—A skeletogram showed mild osteoporosis; W.B.C. 3,900-7,000/cu. mm. (monocytes 8.5-12.5%); serum proteins 6.5-7.2 mg./100 ml. (albumin 3.0-4.4 mg., globulin 2.8-3.5 mg.); normal electrophoresis; latex fixation test weakly positive (Putkonen *et al.*, 1965); urine creatine 460 mg./24 hours (normal 0-50 mg.). Muscle biopsy showed no necrosis or acid-fast bacilli but the characteristics of sarcoidosis—a granulomatous process with small foci of epithelioid cells surrounded by small mononucleated cells and some multinucleated giant cells.

The following investigations showed no abnormality. Blood: haemoglobin, platelets, P.C.V., M.C.H.C., film, L.E. cells, E.S.R., urea, electrolytes, cholesterol, alkaline phosphatase, calcium, phosphorus, liver function, antistreptolysin titre, aldolase, lactic acid

dehydrogenase, creatine, creatine phosphokinase, creatinine, lead, culture. Urine: routine analysis, bile derivatives, porphobilinogen, uroporphyrins, Bence Jones protein, calcium, creatinine, renal steroid leucocyte excretion, intravenous pyelogram. Throat swab, culture for tubercle, 1:10 tuberculin test, Wassermann reaction, V.D.R.L., cerebrospinal fluid, electrocardiogram, Kveim test, radioactive iodine uptake.

Treatment was begun in February with prednisone, 15 mg. daily, reducing to 10 mg. daily in June, the only available therapy of value (Crompton and MacDermot, 1961; Silverstein *et al.*, 1965). After three weeks she could sit up unaided, and by April felt much improved and could walk 30 yards (27 metres) with support. Power had improved considerably in her legs and was normal in her arms apart from slight weakness in her right fingers. In June she was walking up to 100 yards (90 metres) with slight support.

Though remissions occur in the sarcoid process, I thought that, since the condition had progressed inexorably for 15 months, corticosteroid therapy had caused rapid improvement.

COMMENT

The skin lesions of sarcoidosis were first described by Boeck (1899), and literature has amassed covering involvement of nearly all the tissues in the process (Maycock *et al.*, 1963). The diagnosis of sarcoidosis should always be confirmed by histology (Maycock *et al.*, 1963), usually accompanied by an intermittent monocytosis, eosinophilia, leucopenia, raised serum calcium and globulin, and occasionally a raised alkaline phosphatase. A positive Kveim reaction occurs in 60% of patients, with false-negative results in long-standing or inactive disease (Siltzbach, 1964) and during corticosteroid therapy.

The outcome of sarcoidosis is usually spontaneous remission, but irreversible lung or myocardial fibrosis may cause death. Treatment with A.C.T.H. or corticosteroids may produce remission (Silverstein *et al.*, 1965), but 60% of patients do not respond (Crompton and MacDermot, 1961).

Since Sundelin's (1925) original report several cases of muscular involvement in generalized sarcoidosis have been described, taking several forms—asymptomatic microscopic granulomata, palpable nodules, or myopathic. A purely myopathic presentation is very rare, only 12 cases have been found in the literature (McConkey, 1958; Hinterbuchner and Hinterbuchner, 1964). Muscle biopsy shows characteristic sarcoid histology—interstitial infiltration with giant cells, epithelioid cells, and lymphocytes, with tissue replacement by a pallisade-like and reticular collagen fibre network, leading to fibrosis. Occasionally widespread muscle fibre degeneration

occurs with floccular necrosis and macrophagia or epithelioid tubercles and intramysial multinucleated giant cells (Coërs, 1967).

I am grateful to Dr. T. Grahame-Wilson for allowing me to study this case, and to Professor W. Blackwood, Dr. G. M. Churcher, Dr. H. Greenbergh, and Miss J. K. Bowman for their help and advice.

Transfusion Malaria in a Man with Christmas Disease

Brit. med. J., 1967, 4, 466

Malaria as a complication of blood transfusion has been reported in the United Kingdom only four times (Thomas *et al.*, 1936; Nabarro and Edward, 1939; Rogers, 1947; Grant *et al.*, 1960), though it is a relatively common occurrence in countries where malaria has until recently been endemic. The rarity of this complication in England can make diagnosis difficult, as is illustrated in the following case.

CASE REPORT

An Englishman aged 33 who had never travelled abroad had been admitted to hospital many times since childhood for haemarthroses and haematuria, secondary to Factor IX deficiency. He was first admitted to the Churchill Hospital on 14 April 1966 for the treatment of a haematoma in the arm caused by an intramuscular injection.

Examination showed a pale, anxious man with a large tense haematoma of the deltoid muscle. His haemoglobin was only 47% (6.9 g./100 ml.), though he had been given 3 pints (1.7 litres) of blood during the previous week. Investigation revealed chronic renal disease with raised blood urea and proteinuria; an intravenous pyelogram later showed small contracted kidneys. Coagulation studies showed Factor IX deficiency.

The deltoid haematoma was treated during the next two weeks by the infusion of three doses of Factor IX concentrate (equivalent to 1.5–3 litres of fresh plasma), three doses of plasma (dose volume 800 ml.), and packed cells from 4 pints (2.3 litres) of blood. The latter was given on 14 and 15 April. Three more doses of plasma were given later for the treatment of haemarthroses.

He was discharged home on 4 June, only to be readmitted on 17 June with a haemarthrosis of the knee of five days' duration. This was treated by immobilization without intravenous therapy.

On 29 June he developed an unexplained irregular fever and at the same time became hypotensive and developed pancytopenia and splenomegaly.

Investigations from 30 June to 5 August.—The following tests gave normal results: blood, urine, stool, and throat-swab cultures; chest x-ray examination; salmonella and brucella agglutinations; L.E. cell preparations; one search for malaria parasites; a sternal marrow puncture; and cultures of marrow and urine for tuberculosis. During July his anaemia was aggravated by recurrent haematemesis associated with rigors. Thrombocytopenia probably contributed to the gastrointestinal bleeding (platelets 45,000–120,000 cu. mm.). He was transfused with fresh packed cells from 10 pints (5.7 litres) of blood during this time. Meanwhile he developed boils on his buttocks and his blood urea rose from 100 to 186 mg./100 ml. After four weeks of irregular fever the temperature chart began to show a regular periodicity with two clear days between each attack. The character of the fever became strongly suggestive of quartan malaria, and on 5 August parasites of *Plasmodium malariae* were found in the peripheral blood. A review of blood films showed that parasites first appeared in small numbers

in a blood film on 5 July, while six previous films between 3 April and 1 June failed to show parasites.

Chloroquine 500 mg. followed by 250 mg. daily for three days and primaquine 15 mg. base daily for 14 days were given. During the writing of this paper I have been informed that malaria transmitted by blood transfusion does not give rise to exoerythrocytic forms of the parasite. Treatment with primaquine was therefore unnecessary (P. G. Shute, 1967).

Blood counts returned to normal, the boils healed, and the blood urea fell to its former level. During the next three weeks five doses of plasma (dose volume 800 ml.) were administered for haemarthroses, which developed during mobilization, and the patient was discharged home on 10 September.

COMMENT

Investigation of the blood donors in this case revealed one Englishman who had suffered malaria in 1946 while serving with the Army in the Far East. He had been in good health since that time. During prolonged searches of his blood films one young malaria parasite was found. This donor had given 34 pints (19.3 litres) of blood in the past and an attempt was made to discover whether previous recipients of his blood had contracted malaria. A temperature chart suggestive of quartan malaria was found in the records of one recipient 39 days after transfusion. This could not be confirmed on the only available blood film.

In a series of 36 cases of transfusion malaria studied by Lepeš (1965) in Yugoslavia the incubation period varied between 5 and 70 days, the infected blood having been stored 1 to 10 days. The incubation period in the present case was 74 days, the blood having been stored 10 days.

Transfusion malaria should thus be remembered when a patient develops a pyrexia of unknown origin as late as 10 weeks after receiving blood, for in spite of the precautions taken by the National Blood Transfusion Service the occasional donor may be a chronic malaria carrier.

I would like to thank Professor R. G. Macfarlane for encouraging me to publish this case; Professor P. B. Beeson for helping to make the diagnosis; Dr. Jean Grant, who investigated the blood donors; Dr. F. G. Bolton, Mr. P. G. Shute, and Dr. F. E. Lipscomb, who spent much time studying blood films from the patient and donors; and Dr. W. d'A. Maycock for his helpful advice.

Current Practice

DISEASE OF THE DIGESTIVE SYSTEM

Postgastrectomy Problems—II

J. ALEXANDER WILLIAMS,* CH.M., F.R.C.S.

(Last week Mr. Williams considered the cause and management of some symptoms arising after partial gastrectomy. The article continues with an account of other common complaints.)

Loss of Weight

Many patients lose weight or fail to gain weight after gastrectomy. Those who are undernourished at the time of the operation seem to be at the greatest risk.

Some degree of malabsorption of food is common after gastrectomy. It is only a malabsorption of fats that is important. Carbohydrate digestion and absorption as judged by xylose and glucose absorption tests are almost always normal. Although intestinal intubation studies have suggested that protein digestion is impaired by gastrectomy, it is unknown for protein deficiency to occur as the result of gastrectomy provided that oral intake is normal and there is no excess loss. Malabsorption of fat is the easiest form of malabsorption to detect, as the residuum is passed relatively unaltered and can be measured in the faeces. The normal person on an average intake excretes in the faeces no more than five grammes of fat per day. After partial gastrectomy the average daily output of fat in the faeces is from seven grammes (with a Billroth I anastomosis) to ten grammes (with a Billroth II anastomosis).

It is the diminished intake that is the most important cause of weight loss after gastrectomy. The causes of the diminished intake are: lack of appetite, early satiation after a small quantity of food, and fear of provoking postcibal symptoms. The analysis of these three factors is the initial step in the evaluation and treatment of weight loss.

Appetite.—This is determined by a number of apparently unrelated factors, including low blood sugar, empty stomach, and feeling of mental and physical wellbeing. The patient may have a poor appetite because he takes too much tobacco or alcohol or because he is deficient in minerals or vitamins. Iron deficiency is particularly likely to impair the appetite, so to a lesser extent do deficiencies of vitamin B₁₂ and folic acid. In the correct evaluation of the postgastrectomy patient all these factors must be assessed. Treatment may not be easy, particularly of those patients who poison themselves with nicotine or alcohol. For those who suffer from, but do not deserve, a poor appetite even after the correction of deficiencies some form of gastric stimulation before meals may be advised. The French gastroenterologist will advocate a glass of wine, the American chilled orange juice, while the British adviser may prefer sherry.

Early satiation will depend on the size of the gastric remnant, its speed of emptying, and its ability to distend. The more radical the gastric resection, the greater the likelihood of loss of weight. This is a generalization that needs qualifica-

tion and it is unwise to suggest treating weight loss due to a feeling of fullness after meals by reoperation to increase the size of the gastric remnant.

The ability of the gastric remnant to dilate without symptoms may be related to the health of the gastric mucosa. There is a good correlation between the presence on biopsy of atrophic or inflammatory gastritis and the symptom of fullness after meals. General nutritional measures to improve appetite may also increase the capacity to take food. Nevertheless, the simplest way to overcome early satiation is to take small, frequent meals. This is the oldest and simplest of the pieces of advice offered to patients after gastrectomy, but it is still the best.

Fear of Discomfort.—Some of the most severe malnutrition after gastrectomy occurs in patients in whom oesophagitis and regurgitation were provoked by taking food. The patients sought relief from these distressing symptoms in the only way they found effective—by starvation. Treatment is that of the responsible symptom.

Severe malabsorption is relatively uncommon after gastrectomy and always suggests additional disease. This may be pancreatic insufficiency, jejunoileic fistula, regional enteritis, gluten enteropathy, or the intestinal blind loop syndrome.

Diarrhoea

Increased frequency of bowel action is common after gastrectomy, and to many patients cured of both dyspepsia and constipation this is an added bonus of the operation. Many patients complaining of loss of weight, faintness, or vomiting also complain of diarrhoea, though the diarrhoea is not usually disabling.

Some of the important causes of increased frequency and fluid consistency of stool after gastric resection are: increased small bowel transit time resulting from the loss of the gastric emptying regulation once the antrum and pylorus are removed; the osmotic cathartic effect of large quantities of hypertonic foodstuff arriving in the jejunum and attracting fluid into the lumen; the production of large bowel irritants within the gut. Probably the most important factor in this mechanism is the breakdown of bile salts by bacteria. In addition to depriving the digestive tract of an effective emulsifying agent, this breakdown of bile salts liberates powerful colonic irritants which cause diarrhoea. The impaired enzymatic digestion of foods provides more fuel for fermentation and bacterial breakdown in the gut.

As all these factors are present to some extent in all patients after gastrectomy, it is not surprising that mild upsets of bowel habit are common. The practical policy of management is to treat all with simple empirical methods and to reserve sophisticated investigations for those with severe and unremitting symptoms.

* Consultant Surgeon, United Birmingham Hospitals, External Scientific Staff, Medical Research Council.

Diet.—The oldest gimmick known to gastroenterologists is to inquire if any particular food causes diarrhoea and advise its avoidance. Milk and milk products are the commonest provoking agents. The avoidance of all milk products for a trial of two weeks and then observation of the provocative effect of a glass of raw milk should indicate those patients who are sensitive to milk.

Absorbents.—The safest medicaments are the methylcellulose group of water-absorbing compounds. If they produce symptomatic control they can be used indefinitely.

Sedatives.—Sedatives of the codeine or diphenoxylate type can be used and many patients are so controlled permanently. Because of the dangers of habituation they should be used with caution.

Antibiotics.—A short course of broad spectrum antibiotics will often control an attack of diarrhoea. The agents effective against the gram-negative organisms are the most useful, presumably because they abolish or alter the flora of the upper gastrointestinal tract, and in particular control those organisms that cause breakdown of bile salts.

Neomycin, which is not normally significantly absorbed from the alimentary tract, is the safest for prolonged administration, though even this drug may cause mucosal damage. Combinations of tetracycline and nystatin may also be used. Prolonged therapy rarely produces prolonged relief, but intermittent antibiotic therapy may help to control symptoms.

The investigation and treatment of severe or intractable diarrhoea is best accomplished in a specialized gastroenterological unit. Gastrojejunal fistulae may be due to recurrent ulceration. This is investigated by barium enema and barium meal examinations as well as acid secretion studies to evaluate the cause of the ulceration.

Pancreatic insufficiency is investigated by pancreatic function studies with duodenal intubation and hormonal stimulation of the pancreas.

Gluten enteropathy may be demonstrated by peroral jejunal biopsy. The intestinal blind loop syndrome is studied by intestinal aspiration and culture and vitamin B₁₂ absorption tests.

Faintness

The feeling of faintness after meals is the predominant symptom of the so-called "dumping syndrome." The faintness occurs within thirty minutes of taking food and is usually accompanied by one or more of the following symptoms: flushing, sweating, palpitation, anorexia, nausea, and sometimes colic and diarrhoea. This combination of symptoms may occur after any gastric resection, even after pyloroplasty, but is usually worse if there is a small gastric remnant that empties rapidly. After partial gastrectomy almost all patients experience some of these symptoms at some time in the early months after operation, but in most the symptoms are transient. Prolonged complaint of annoying or disabling symptoms occur in less than 5% of most reported series.

The term "dumping" was first used by Mix,³ in 1922, who believed that the symptoms were produced by food being dumped straight into the small bowel. The physiological implications of this syndrome are so fascinating that an increasing amount of research has been devoted to its study. This work has all confirmed Mix's original concept, but it is only in the last five or six years that there has been much significant advance.

There are three essential features of the phenomenon of dumping. The small bowel cannot handle the glucose load of a meal "dumped" into it straight through the stomach. This results in the osmotic retention of large volumes of fluid in the gut with a consequent fall in blood volume, usually greater than 10%.

Symptoms are produced by distension of the small bowel and may occur even if the blood volume is maintained at normal levels by rapid transfusion. The humoral role of serotonin has been postulated but its aetiological significance is not proved.

These symptoms tend to occur in patients who can be shown preoperatively to have a predilection to dumping. These same patients have a more than average incidence of allergic diseases such as hay-fever or asthma. They are also said to have a less than normal mental and emotional stability.

Certain additional observations about these patients help us to keep this problem in perspective. Patients with dumping often develop these symptoms after several symptom-free years. The symptoms are not always constant and they may have weeks or even months of freedom at a time. Dumping is rarely seen in a patient who is otherwise fit and mentally stable.

It will be seen from these observations that any purely mechanistic theory of aetiology cannot be the whole explanation, and a purely mechanistic approach is unlikely to succeed.

Special investigations in these patients are of little practical value in determining the type of treatment and should be employed only if their purpose is to advance knowledge. There is no practical value in determining whether a patient has hyper- or hypoglycaemia during an attack, nor what type of glucose tolerance curve they have, nor yet whether the barium meal empties rapidly from the stomach. Exactly comparable results to these tests would be obtained from many asymptomatic postgastrectomy patients.

Treatment is, once more, empirical on a progressive scale, the first treatment for the least severe and earliest cases.

Reassurance.—Most patients who, soon after operation, experience faintness after meals require nothing more than an explanation and reassurance. They may be reassured that their symptoms are likely to become less and will probably disappear in the coming months.

Correction of Deficiencies.—It is essential in the management of any postgastrectomy problem to consider the possible role of mineral and vitamin deficiencies. Iron deficiency is the commonest abnormality found after gastrectomy and may predispose to "dumping" symptoms. Vitamin B₁₂ and folic acid deficiencies should also be sought and corrected.

Diet.—In addition to reassurance and iron therapy, simple dietary measures may be advised. These are sufficient to control most mild symptoms. Rather than eating, as many do, one main meal each day, the patient should be advised to take three small meals, and, unless obesity is a problem, to take a small snack between each meal. Large carbohydrate meals should be avoided and the caloric intake should be made up with proteins and fats. Restriction of fluid intake at mealtimes also helps to delay emptying of the gastric remnant and relieves symptoms.

Advice to lie down or rest after a meal may be useful in the immediate postoperative period, but is impracticable once the patient returns to work.

Drug Therapy.—The appreciation of the aetiological role of impaired intestinal handling of glucose and the observation⁴ that in patients with "dumping" insulin given before meals prevents symptoms have led to a most significant new therapeutic approach with oral hypoglycaemic drugs. Tolbutamide 500 mg. before each main meal will often control symptoms, and should be a first line of treatment in the patient with severe symptoms. Some success has been claimed with anti-serotonin drugs, and Sullivan⁵ advocated 4 mg. of cyproheptadine before meals in addition to or instead of tolbutamide.

Operative Treatment.—The principle behind attempted surgical treatment of patients with "dumping" is the attempt to delay the rate of emptying of the gastric remnant by narrowing the stoma, rerouting the food through the duodenum (by conversion to gastroduodenostomy), or the creation of an

artificial "sphincter" by placing a reversed jejunal loop between stomach and duodenum. There is, however, rarely if ever any need to operate on patients with "dumping."

Conclusions

The patient who complains of pain, nausea, vomiting, weight loss, diarrhoea, or faintness after partial gastrectomy presents a problem that is rarely easy to evaluate. All symptoms tend to be buried beneath a mound of ineffective antacids.

The essential principle of the approach to the problem is to take a careful history from the patient with no preconceived ideas or with no empty mental pigeonholes labelled "——— syndrome" waiting to receive the problem as soon as the patient admits to the first classical symptom. Then evaluate the symptoms, looking for objective evidence of organic disease. The symptoms of pain and vomiting always require a comprehensive series of investigations, whereas loss of weight, diarrhoea, or faintness are best managed initially by simple empirical methods.

In some patients with recurrent dyspepsia after gastrectomy no definite diagnosis will be made or no permanent cure found. Some of these will be psychologically unstable and others will appear to become so as their symptoms remain undiagnosed and unrelieved. This residual group of unhappy complaining patients taxes the sympathy and resources of anyone who has to deal with many postgastrectomy patients. From several years' experience of reviewing many and reoperating on some of these unfortunate patients, I believe that they frequently need sympathy and continued interest but only rarely benefit from reoperation.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Corticosteroids in Pregnancy

Q.—What are the particular hazards in pregnancy and childbirth in primiparae who have been taking corticosteroids continuously for some years for intractable asthma? What may be done to minimize the hazards, and should the baby be given corticosteroids after birth?

A.—The dangers of long-term corticosteroid therapy are due mainly to adrenal suppression, but since pregnancy itself stimulates the adrenals to double the normal secretion of cortisol this effect is minimized.¹ There is usually no need to increase the dose of steroid during pregnancy, but the possibility of steroid deficiency arising during any acute illness remains.

Labour is regarded as any major surgical operation would be, and hydrocortisone is given parenterally throughout this period of stress. Postpartum haemorrhage may produce a more dramatic collapse than in the normal patient, and must be treated with intravenous hydrocortisone as well as blood volume replacement.

Though corticosteroids do cross the placenta, they do not usually produce any noticeable effect on the baby. There is no

reason to give steroids to the baby unless signs of deficiency are manifest.

Patients receiving corticosteroids should be confined in hospital.

Animal Hosts to Rabies

Q.—Do lemurs contract rabies, and are there any other of the rarer infections which they may convey to humans by biting?

A.—The host specificity of rabies virus is low and the range of susceptible species includes man, domesticated mammals, and many wild ones, including foxes, wolves, mongoose, skunks, rodents, and certain kinds of bat. Monkeys can be infected experimentally, and the first natural case was recently recorded¹ in a rhesus monkey (*Macaca mulatta*) which had been imported into Britain from India. Lemurs are primitive primates of the suborder Prosimii. Though I know of no report of rabies in these animals, the possibility cannot be ruled out in view of the wide host-range of the virus, and it should not be ignored because

of the extreme danger attending the bite of an infected animal.

Monkeys may also, while showing trivial or no mouth lesions, harbour herpes B virus (*Herpesvirus simiae*), which, if transmitted to man, causes a serious and usually fatal condition. B-virus infection has been detected in many Old World monkeys,² and, though lemurs have not been examined, the risk of infection should be considered after any bite inflicted by these animals.

Local sepsis or septicaemia resulting from infection by mouth flora are also possible, and it might be remembered that pulmonary tuberculosis, with the production of infective sputum, can occur in captive primates. Extreme caution should be the watchword where primates are being kept. Every effort should be made to avoid contact with the animals or material derived from them, in particular from the mouth, and bites should be regarded most seriously as matters for immediate and thorough surgical attention.

During 1966 only one licence was issued, under the Animals (Restriction of Importation) Act, 1964, for the importation of a lemur—a *Lemur catti* from a French zoo. On the other hand, licences covering more than 20,000 Old World monkeys, required mainly for scientific purposes, were granted.³

Book Reviews

Mental Retardation

The Pathology of Mental Retardation. By L. Crome, M.C., M.R.C.P.(Ed.), M.C.(Path.), and J. Stern, Ph.D. (Pp. 406+viii; illustrated. 84s.) London: J. & A. Churchill. 1967.

In this book a vast amount of information is presented about the pathology of mental retardation and the subject is interpreted in the widest possible sense. The opening chapter is on the genetic causes of mental retardation, paying particular attention to the anomalies of sex chromosomes and including a brief account of the classification of human chromosomes, several karyograms, and the structure of the D.N.A. molecule. A chapter on disorders of gestation follows in which numerous factors are briefly reviewed, ranging from the teratogenic viruses to emotional stress, seasonal fluctuations, and geographical distribution. Here some disappointment may arise, for, although an enormous range of information is given, a brief mention only is made of congenital toxoplasmosis and no detailed account of the pathology of the central nervous system in this infection appears anywhere in the book. In the section on intrauterine infections there is an account of the different abnormalities which occur with maternal rubella and a commentary on advice given to pregnant women contracting rubella. In a brief mention of Coxsackie B virus infection, although a photomicrograph of encephalitis and myocarditis is produced,

no account is given of the pathology of Coxsackie encephalitis in infancy. The part played by birth injury is reviewed and so are the post-natal causes of mental retardation.

The morbid anatomy of mental retardation is detailed in two lengthy sections. In the first the lesions found in the brain in the non-classified forms of mental retardation (the great majority) are described. The descriptions and illustrations of such conditions as micrencephaly, the disorders of cellular migration, gliotic encephalopathy, and cerebral calcification are excellent and the chapter is made more valuable by the figures of the frequency of the occurrence of such lesions in Dr. Crome's personal cases. A short chapter on the non-specific biochemical abnormalities in the body fluids follows and then an account of the specifically recognizable syndromes associated with mental retardation such as Down's disease, the various forms of hydrocephalus, tuberous sclerosis, and the metabolic diseases. The last subject occupies most of the second part of the book and begins with a comprehensive table of the conditions in which mental retardation and metabolic disorder are associated. This summarizes 47 syndromes,

giving their main clinical features, the specific defect where this is known, the main abnormal substances present in the urine or blood or tissues, the mode of transmission, and the key references in the literature. This is followed by an account of the morbid anatomy and chemistry of these disorders. Finally a series of appendices is given. These include a screening procedure and the details of biochemical and histological techniques used in investigating mental retardation and data in table form ranging from organ weights in infancy to the lipid content of unfixed cerebral tissue. Illustrations are well produced and relevant, and the references numerous, of wide range, and admirably recent.

To the pathologist or clinician involved in the care or investigation of cases of mental retardation this book will be invaluable. Few recently published texts will give so much information for the money. The subject is difficult and complicated and it is hoped that the rapid advances of knowledge in the field and the demand for the book will justify further editions. Perhaps the authors would then consider reducing the scope of some of the earlier chapters particularly in which brief reference to so many topics is distracting and may discourage some readers from further careful perusal of a pioneering volume of great value and merit.

B. E. TOMLINSON.

Ancillary Staff in the U.S.A.

A Textbook for Medical Assistants. By M. Murray Lawton, M.D., and Donald F. Foy, B.S., M.S. (Pp. 465+xii; illustrated. 66s.) London: Henry Kimpton. 1967.

This book is by Americans for Americans, but is surprisingly applicable to general practice in the N.H.S. in England. Specialization in the United States is increasing and the general practitioner is a rapidly disappearing phenomenon. This, the authors believe, is unfortunate, and the general public as well as the medical profession are concerned about the drift away from general practice. The American Medical Association is at present studying proposals to elevate general practice to the status of other specialties and make it more attractive to young physicians. The passage of the Medicare Bill will accentuate the need for general practitioners as old people realize the extent of their coverage under the Medicare programme and fill doctors' surgeries with hitherto untreated complaints.

This is precisely the situation which British doctors have faced since 1948, recently accentuated by greater demands by more patients on fewer doctors. The solution to the dilemma lies in better organization of general practice, which implies increasing use of ancillary workers, whom the authors more aptly term medical assistants. These are

people trained to assist the doctor by relieving him of routine responsibilities of running his practice—a combination of secretary, receptionist, nurse, and laboratory assistant doing everything from testing urine to clearing up after patients who have vomited. Fewer than one in every three general practitioners in this country employ even a full-time receptionist, let alone a nurse, despite repayment of 70% of their salaries, and this is partly because doctors are uncertain about what to delegate to them or how to train them. Drs. Lawton and Foy provide information in this book on every conceivable aspect of paramedical work. It includes chapters on the development of scientific medicine, medical ethics and jurisprudence, the correct use of English, and common medical terminology. Its clinical chapters give detailed instructions about blood-pressure readings, routine urinalysis, hypodermic and intravenous injection techniques, and haemoglobin estimations, all illustrated by charts, diagrams, and photographs admirably designed for intelligent lay people.

With the fee-paying American patient in mind the book devotes space to the décor of the waiting-room, flower arrangements, the personal appearance of the staff (so-called beehive hairdos should be avoided), and even the selection of magazines for the waiting-room (biased religious and political publications have no place there), but most of what it says makes sense in the English surgery. It is particularly good on the appointments

system (recent surveys have shown that American patients leave their doctors not because of high fees or failure to cure but rather because of the length of time they are kept waiting) and its advice on first aid in every emergency from simple fainting to acute poisoning is sound.

The day of the single-handed, horse-and-buggy doctor with the battered black bag is over, but his successor has not yet learned how to use non-medical assistants. This is a textbook for him and them.

ANDREW SMITH.

Treating Arterial Disease

Peripheral Arterial Disease. Major Problems in Clinical Surgery. Vol. 4. By Wiley F. Barker, M.D. (Pp. 229+xiv; illustrated. £2 19s. 6d.) Philadelphia and London: W. B. Saunders. 1966.

This short book on peripheral vascular disease has been limited to the problems of arteriosclerosis. Since this forms far away the largest group of vascular disorders this orientation is very proper and the whole emphasis of the book is towards surgeons who will be dealing with these problems. It starts with a rather long chapter on the anatomy of arterial supply, all of which should surely be well known to those likely to use this

book. Then follows an excellent chapter on the physiology and applied physiology of arterial flow. The pathology of atherosclerosis is dealt with clearly, though a future edition might well allow a little larger cover of the aetiological and metabolic background to this disease.

Most of the book is devoted to the clinical examination, investigation, management, and results of treating peripheral arterial disease. It is outstandingly good and packs an enormous amount of useful practical information into a short space. Thus in clinical assessment the much poorer prognosis where tissue necrosis is present is emphasized. The scope of conservative measures and the role of sympathectomy are discussed. The confused position with regard to anticoagulants is clearly stated. When it comes to the technical considerations of direct arterial surgery the book is full of sound advice and any experienced surgeon will recognize the many home truths discussed. The ground covered is far wider than actual operative technique, and an enormous number of small but important side-effects such as hypotension after declamping an artery receive careful consideration.

The book ends, very properly, with a detailed analysis of the results of surgery, which reflects the honesty so apparent throughout the book. This little book will be outstandingly useful to anyone groping with the problems involved in treating peripheral arterial disease.

W. T. IRVINE.

Learning about Viruses

Basic Medical Virology. Edited by James E. Prier, Ph.D. (Pp. 715+ix; illustrated. £5 16s.) Edinburgh and London: E. & S. Livingstone. 1967.

There have been a number of textbooks on medical virology in the last few years, and, although this is a rapidly changing field, it becomes increasingly difficult to justify each new one. The editor of this one is patently aware that it is no longer possible to include all facets of virology in a single textbook, so this book is directed to the preclinical student. In addition to medical and veterinary students, however, there is much to be found to interest the graduate who selects virology as a special subject.

With Dr. Prier teaching in the department of microbiology in Philadelphia, it is perhaps understandable that no fewer than 11 of the 25 contributors are from the medical schools of Philadelphia and all but three contributors come from America. Each has been chosen for his specialist knowledge of the particular subject, and, since their only brief was to provide information for the student, there is a lack of uniformity in the presentation of the chapters. Classifying the viruses so that the chapters may be presented in some logical order is very difficult, but this problem has been solved by discussing them in groups formulated according to physical, chemical, and biological characteristics. There are exceptions to this rule, however, and viruses inadequately classified or those causing diseases of particular biological or economic significance are dealt with individually.

The basic sciences for the understanding of virus activity are well presented. The chapter on physical and chemical properties of viruses is easy to read. Although the presentation of the laboratory techniques for the cultivation of viruses is always very difficult, the student will certainly be better informed after reading this chapter. The pathology of viral infections, and especially the host-parasite relationship, are well explained, and the chapter on immunity deals with every aspect, citing nearly 300 references. The chapters dealing with particular groups of viruses are packed with data and references, and the only criticism to be made is that some tend to be short sentences joining together an oversized bibliography that is neither interesting nor easy to read. It is a pleasure to see the difficult subject of oncogenic viruses so well presented, since this will have particular interest for the student of virology today.

The diseases dealt with individually are rabies, rubella, infectious and serum hepatitis, lymphocytic choriomeningitis, hog cholera, and bovine virus diarrhoea. Although the selection of some diseases that have had separate treatment is obvious, the choice of others can only be on the grounds of inadequate classification. The last five chapters, dealing with all viruses of particular interest to an animal species, are most useful. Thus ovine, avian, feline, and canine, bovine, equine, and porcine viruses, as well as virus diseases of fish, are presented separately.

In a book of this kind there is bound to be some overlap of subject matter and differences in presentation. Nevertheless, the book is an up-to-date collection of facts and it

has a good index. The preclinical student of medicine will find it a very useful reference book, but it certainly goes beyond his needs in subject matter and price. Many research workers will wish to use it for reference purposes, and thus it should find a place in all good libraries.

FRANK T. PERKINS.

Anarchy

The Clerkenwell Riot. The Killing of Constable Culley. By Gavin Thurston. (Pp. 188+xv; illustrated. 28s.) London: George Allen & Unwin. 1967.

In an age when anarchistic forces of various kinds are working with considerable success in civilized societies it is of some interest to read a detailed account of the sort of situation that these forces ultimately produce.

In 1833 a policeman was murdered and some of his colleagues injured in a clash at a low-grade political meeting at Cold Bath Fields, off Grays Inn Road, London. At the coroner's inquest on the dead policeman the jurors made themselves national heroes by taking command of the inquiry, harrying police witnesses, and encouraging witnesses willing to recount tales of police brutality. Following their verdict of justifiable homicide the jury were feted and medals struck for them. Their popularity was, if anything, increased by the quashing of their verdict by the Court of King's Bench.

Throughout the account of this *cause célèbre* the frightening theme is the almost complete absence of any popular support for the forces of law and order, save from the remarkable men who were concerned with developing the new police force.

On another level, Dr. Thurston shows what an appalling spectacle can develop when a judicial inquiry gets out of hand. The weakness of the presiding coroner was itself an enemy of law and order. By his failure to control the pigheaded tradesmen defying authority in the limelight of the jury box more harm was done than by the forbidden meeting of workmen which sparked off all the fuss.

Dr. Thurston tells a gripping as well as a well-documented tale of an incident insignificant in itself in history, but interesting and important as a symptom of the *malaise* of a nation.

Clinicopathological Conference

A Case of Cushing's Syndrome with Misleading Urinary Steroids

DEMONSTRATED AT THE ROYAL POSTGRADUATE MEDICAL SCHOOL

Clinical History

Dr. C. L. COPE: The patient (Case No. 297379; P.M. No. 11154) we are considering today was a housewife aged 45 at the time of her death.

She was well until 1950, when she developed diabetes mellitus with thirst, polyuria, and loss of weight starting three months after the birth of her only child. She was started on insulin therapy at this time. In 1956 she was found to be hypertensive and in 1958 she was admitted to hospital because of tiredness. Her blood pressure was then 180/110 mm. Hg and at subsequent outpatient attendances the diastolic pressure varied between 120 and 150. By 1960 she was feeling more tired. She now had dyspnoea on exertion and intermittent swelling of her ankles. She had attacks of orthopnoea and she herself noted rounding and redness of her face, with growth of hair on both face and chin. She had also noticed that her abdomen had got larger but that her extremities were thinner. Her menses were regular. She reported easy bruising of her skin. Her diabetes was stabilized on a 1,800 calorie diet with 48 units soluble insulin and 24 units P.Z.I. each morning.

In 1961 she was admitted to a teaching hospital, where typical Cushingoid skin, facies, hirsuties, buffalo hump, and easy bruising were all noted. At that time she also had oedema of ankles and sacrum. Her blood pressure was 150/120 mm. Hg and there were bilateral basal crepitations in the chest. There was marked muscle weakness and muscle wasting. The clinical conclusion was "this should be Cushing's syndrome."

Accordingly, tests to confirm the clinical diagnosis were done. But the levels of urinary oxogenic steroids were 8.3 and 16 mg. and those of 17-oxogenic steroids were only 12.3 and 15 mg., analyses being done in two separate laboratories. A presacral air insufflation was not sufficiently clear for a useful opinion of adrenal size to be given, and the response to four days of corticotrophin was reported as being in the normal range, the level of 17-oxogenic steroids rising to 70 mg. on the fourth day.

She was discharged free of oedema on a regimen which included insulin, digitalis, guanethidine, reserpine, chlorothiazide, and potassium chloride. The diagnosis made was diabetes mellitus with essential hypertension.

By 1962-3 she had become irritable and restless and her memory was poor. Her menses were scanty and her exercise tolerance had become smaller still. By March 1964 her amenorrhoea was complete.

In October 1964 she was admitted to hospital elsewhere because of three to four months of attacks of nocturnal dyspnoea. She now had what was described as a typical Cushingoid appearance, though without striae. There was congestive cardiac failure and she had attacks of acute pulmonary oedema in which the blood pressure rose to 240/140 mm. Hg. The fundi showed pin-point haemorrhages but

no exudates or papilloedema. There was glycosuria but no albuminuria or ketonuria. The haemoglobin was 14.4 g./100 ml., with a W.B.C. 14,200, of which polymorphs were 89% and eosinophils 1%. The blood urea was 49 mg./100 ml. The urinary 17-oxosteroids were reported as 32 mg. but 17-oxogenic steroids as only 4.7 mg. She was treated with digoxin, mersalvi, cyclopentiazide, and methyl dopa, but made relatively little improvement.

Final Admission

She was transferred to Hammersmith Hospital on 10 December 1964. By now she had ceased to have attacks of pulmonary oedema, but her pulse was 140 and regular. The blood pressure was 150/114 mm. Hg and the jugular venous pressure was +1 cm.

There was now a heavy albuminuria and the blood urea was 60 mg./100 ml. The plasma sodium was 13, potassium 3.3, bicarbonate 34, and the chloride 88 mEq/l. The blood sugar varied between 200 and 320 mg./100 ml. The urinary calcium loss was 220 mg. daily.

X-ray studies showed an enlarged heart with several healed rib fractures in thin bones. The spine showed no evidence of vertebral collapse. The skull was thought to show osteoporosis; the sella turcica was not enlarged but did show asymmetry of its floor.

There was calcinosis in the pulp of several fingers and the thumbs. There was also extensive destruction of the articular surface of the distal interphalangeal joint of the right index finger.

Steroid studies left no doubt of the existence of a severe degree of Cushing's syndrome. The 17-oxosteroids were normal, as is commonly found (11.7 and 12.7 mg.), but the 17-oxogenic steroids were raised at 23 and 34 mg. The levels of plasma 11-hydroxycorticoids (cortisol) were 30.5 μ g. at 9 a.m. and 28.5 μ g. at midnight, a very high figure. The urine level of 11-hydroxycorticoids was 1,600 μ g. daily and the urine true cortisol was 580 μ g. a day, both values being about three times the upper limit of normal. The plasma levels of 11-O.H.C.S. after five days of suppression with 8 mg. of dexamethasone daily were not reduced, the morning value being 37 μ g. and the midnight 24 μ g. Suppression was therefore not observed. But the adrenals were shown to be corticotrophin dependent by a rise of 17-oxogenic steroid excretion to 93 and 118 mg. after metyrapone in a dose of 4.5 g. daily.

Management

Her glycosuria was fairly well controlled by soluble insulin and P.Z.I., but because of her borderline left ventricular failure she was not considered fit for major surgery or even for air

FIG. 1.—Hyperplastic adrenal cortex. (H. and E. $\times 5.4$.)

FIG. 2.—Coronal section of pituitary fossa. (Picro-Mallory. $\times 7$.) The carotid arteries are present at either side, the dark central mass is haemorrhagic and necrotic tissue. The holes (2 and 3) are the site of the yttrium seeds. The tumour (1) partly surrounds the right internal carotid artery.

FIG. 3.—Coronal section of pituitary fossa. (Picro-Mallory. $\times 60$.) The bony floor of the fossa is being eroded by an invasive pituitary tumour.

FIG. 4.—Focus of fibrosis in one papillary muscle. (H. and E. $\times 45$.)

FIG. 5.—Small artery, from myocardium adjacent to Fig. 4, showing a lumen almost completely obliterated by atherosclerosis. (H. and E. $\times 70$.)

FIG. 6.—Renal glomerulus showing hyaline change in the afferent arteriole at the base of the tuft, and some diffuse stromal thickening. (Marsius Scarlet Blue. $\times 450$.)

insufflation. On 22 January a pituitary implant of yttrium-90 was inserted by Dr. M. Hartog.

On 25 January the plasma level of potassium was 2.5 mEq/l., although she was receiving 3 g. of potassium chloride four-hourly. The sodium was 141, bicarbonate 39, and chloride 74 mEq/l. The blood urea was 42 mg./100 ml. On 27 January she felt fairly well, her blood pressure was 150/90, but she had attacks of palpitation. The plasma potassium had fallen to 2.1 mEq/l., and intravenous potassium chloride in 5% dextrose was given at 20 mEq per hour until the plasma potassium was raised to normal.

The urinary 17-oxogenic steroids were still raised, figures of 38, 46, and 31 mg. being found.

On 28 January she suddenly collapsed at 7 a.m., an E.C.G. showing ventricular tachycardia. Therapy with procainamide, mephentermine, and cortisol resulted in restoration of sinus rhythm, but a tendency to ventricular ectopic beats persisted. She was soon restored to full consciousness and was well enough to start breakfast. At 9.30 a.m. she had a further sudden collapse, this time due to asystole. The electrical defibrillator was of no avail and she died.

Clinical Diagnoses

- (1) Left ventricular failure.
- (2) Hypertensive heart disease.
- (3) Cushing's syndrome, due to hyperplasia.
- (4) Diabetes mellitus.
- (5) Suspect Kimmelstiel-Wilson kidney.
- (6) Yttrium implant.

Post-mortem Findings

Dr. E. D. WILLIAMS: On examination this woman was rather short and showed the features of Cushing's syndrome described in the clinical presentation.

Both *adrenals* were enlarged (10 and 11 g.) with diffusely hyperplastic cortices (Fig. 1), in which microscopical study showed compact cells extending out to the zona glomerulosa. The *pituitary* was removed with the surrounding bone (Fig. 2), and sectioned after the centrally placed yttrium rods had been removed. The tissue around the rods was necrotic and haemorrhagic. On the left side the peripheral part of the anterior pituitary survived, though it was somewhat haemorrhagic. In this area numerous hyaline basophils (Crooke cells) could be identified. On the right side there was a tumour (Fig. 3), about 6 mm. in diameter, in the lateral part of the lobe, extending laterally into the cavernous sinus, with a tongue of tumour spreading above and below the carotid artery. Microscopically the tumour was a chromophobe adenoma, with a few cells containing basophil granules. Scattered cells in the tumour showed hyaline pale blue cytoplasm with the Crooke-Russell technique. The floor of the pituitary fossa showed only a single small area of invasion by the tumour. The dorsum sellae was intact, and there was no meningitis.

The *parathyroids* were slightly enlarged but showed the normal ratio of glandular cells to fat. The *thyroid* was normal. The *pancreatic islets* were enlarged but did not show any hyaline degeneration. The pancreas otherwise was very autolysed but did show very prominent centroacinar cells. Numerous hyaline arterioles were present.

The *heart* was moderately enlarged (480 g.), with marked left ventricular hypertrophy (2 cm. thickness). The valves were essentially normal. On microscopy there were small scattered areas of fibrosis throughout the myocardium, and a single small old infarct about 3 mm. in diameter in the left posterior papillary muscle (Fig. 4). This showed central scar-

ring, while some adjacent muscle bundles showed nuclear and cytoplasmic changes suggestive of recent extension of the old infarct. A small artery (Fig. 5) adjacent to this was virtually occluded by atheroma. The main coronary arteries showed non-occlusive atheromatous plaques. The aorta showed moderate atherosclerosis with calcification and ulceration in the lower abdominal aorta.

The *lungs* were oedematous but otherwise normal. On section a single asbestos body was an unexpected chance finding. In the alimentary tract the stomach showed recent mucosal haemorrhage; the large and small intestines were normal. The *liver* (1,775 g.) showed a large yellow clearly demarcated subcapsular area, a localized area of fatty change.

Both *kidneys* were of normal size and macroscopic appearance. Microscopically the glomeruli showed a mild diffuse stromal thickening (Fig. 6) but no nodular lesions of Kimmelstiel-Wilson type. The afferent glomerular arterioles showed a prominent hyaline change and a few proximal convoluted tubules showed coarse vacuolation attributable to hypokalaemia.

Several healed *rib* fractures were present. Sections of the vertebrae showed moderate osteoporosis. In the sections of one interphalangeal joint there was almost complete loss of the joint cartilage, with eburnation of the underlying bone. Considerable new bone formation was present.

In the *eye* sectioned there was hyalinization of some choroid vessels, and one retinal capillary showing aneurysmal dilatation.

Pathological Diagnosis

- (1) Chromophobe adenoma of pituitary.
- (2) Bilateral adrenal cortical hyperplasia.
- (3) Left ventricular hypertrophy with patchy fibrosis and a small infarct of one papillary muscle.
- (4) Mild diffuse diabetic glomerulosclerosis.

Discussion

Dr. COPE: I admit that I left out originally the diagnosis of diabetes mellitus. Whether we should call that part of the Cushing's syndrome or not I do not think we can answer here. We did not know enough about this patient before she came to us in her terminal illness. If successful treatment of the Cushing's syndrome had greatly relieved the diabetes we could have included it in the Cushing's syndrome. I think we might have made a case for her having separate diabetes mellitus, but I think it is largely speculative. She had a heavy albuminuria, and I would have expected that she would have shown some Kimmelstiel-Wilson changes. But the fact that she did not leaves the albuminuria unexplained unless we attribute it to the severe hypertension. To me the main interest of this patient by far is the events that happened in 1961, when an expert clinician and an endocrinologist came to the clinical conclusion that this should be Cushing's syndrome. But too much reliance was placed on laboratory diagnostic tests, which, even at that time, were known to be very fallible. The clinical impression was completely overruled and a final diagnosis of diabetes with independent essential hypertension was made. There is a very good object lesson here, I think. No one should interpret a diagnostic laboratory test to the point of taking action on it unless he knows how valid it is. Surely one of the functions of a clinician these days, an admittedly difficult one, is to seek evidence for the reliability or otherwise of the vast numbers of laboratory tests that are poured out every day. Urinary 17-oxogenic steroid assays are known to be fallible, and a whole series of them seem to have been misleading on this one single patient. In

such circumstances the physician should relinquish his clinical impression with reluctance.

However, there are other points about the case; there are indeed many. We were handicapped in many ways by the fact that she was so ill, and that we therefore did the minimum with her in the way of investigation. She was strongly suspected to have an adrenal hyperplasia, pituitary-dependent. The sella turcica was practically normal in x-ray, but there was asymmetry of the floor of the sella which was compatible with the development of tumour formation.

Dr. J. LAWS: No, I wouldn't agree there. The report said that there was asymmetry of the floor of the fossa and suggested tomography. This confirmed that the fossa was not enlarged.

Dr. COPE: Maybe that was the order of events. You were quite right to suggest that tomography of the floor may be helpful. Unfortunately we have not got those pictures, but one of the things to discuss is the extent to which x-ray tomography can give an indication of the degree of invasion. As I was looking at the films it struck me that she was a candidate for a meningitis in the near future. I have seen that happen before in a patient diagnosed as a diabetic. A pituitary tumour was found eroding into the sphenoidal sinus, producing a meningitis which complicated the whole clinical picture.

Another aspect of interest is the potassium troubles which she had towards the end. They were admittedly terminal, but we were very conscious of them. We were unable to keep her plasma level of potassium up and we didn't know why. It is possible that she had been severely potassium depleted before she came to us. The final circumstances of her cardiac breakdown are also worth discussion: ventricular tachycardia on the one hand—the type unfortunately unspecified—and the final asystole from which she never recovered.

Importance of Clinical Diagnosis

Professor Sir JOHN McMICHAEL: I think, as Dr. Cope has emphasized, this case is full of lessons. The important part of the diagnosis of Cushing's syndrome is really clinical. The laboratory tests, now of course more refined, could be misleading. I would like to get the record straight: it was reported in the other hospital in 1964 that she had no albuminuria. Did she develop it in the later stages?

Dr. COPE: She had it all the time she was with us from 10 December until her death on 28 January.

Professor McMICHAEL: I see. On those grounds—albuminuria in a diabetic—together with the evidence of aneurysms of the retina and hypertension, one must make the diagnosis of Kimmelstiel-Wilson syndrome; but, as has been shown by Dr. Williams, there were no characteristic glomerular lesions, though there was some thickening of the basement membrane.

Dr. WILLIAMS: There was a diffuse stromal lesion in the glomerulus, not truly a basement membrane thickening.

Professor McMICHAEL: So the glomeruli did show something which I presume could have antedated heavier deposition?

Dr. WILLIAMS: Yes, indeed this could have been responsible for the albuminuria. At the time it was detected, however, she was also a hypertensive in heart failure.

Unusual Infarction

Professor McMICHAEL: The other thing that is of great interest to me is that she had evidence of a small infarcted area in the capillary muscles of her heart without gross obstruction of the main coronary arteries on the surface of the heart. Now this is rather exceptional. Generally speaking, the basis of coronary disease is occlusion—and occlusive changes in the visible vessels on the surface. Very seldom do occlusive changes develop in the penetrating branches of the coronary artery. An

infarcted area is usually related to obstruction of the surface vessels. This is the first time I can recollect seeing an infarct due to occlusion of the penetrating branches of the coronary arteries running in towards the papillary muscles. That will no doubt call for comment from Professor Harrison.

Professor C. V. HARRISON: I'm casting my mind back to the various cases I have seen with very small vessels involved. They have all been in cases of polyarteritis nodosa. They have been still visible on the surface of the heart, so that they were not the ones that dip down into the muscle.

Dr. J. P. MOUNSEY: Can I make another point? We are told that the necropsy showed infarction of a papillary muscle. Functional mitral incompetence sometimes accompanies this anatomical lesion. Was there in life at any time a systolic murmur?

Dr. COPE: Not one of any significance. There may have been a slight one, but there was none recorded, and I have never heard one myself.

Professor McMICHAEL: There has to be considerable loss of function to the papillary muscle for that to occur. It may be ruptured or it may be unable to contract, so that the cusps may be blown out to give a systolic leak.

Dr. MOUNSEY: I wanted to know whether what we have been shown was purely of morbid anatomical interest or also of physiological and functional interest.

Dr. WILLIAMS: I should comment that it was only a small infarct, perhaps a third of the area of the papillary muscle in section. I wondered whether in the papillary muscle the blood supply was more tenuous, depending on a single artery rather than several anastomotic branches. This, therefore, may be a special case. I would like to stress that it was a small infarct; there were numerous smaller areas of fibrosis, which one could not dignify with the name of infarct, scattered over all the sections of the left ventricle.

Dr. COPE: If there was only such a very small infarct, why did she have hypertensive heart failure?

Professor McMICHAEL: Hypertension as such can cause overload failure.

Dr. COPE: I don't think that's an adequate explanation.

Professor HARRISON: May I throw a spanner in? We are fooling ourselves by equating the word fibrosis or necrosis and the word infarct. Now, may I refer you to the work of Mitchell and Schwartz,¹ of Oxford, who analysed these small lesions in the myocardium. They found that the big ones were constantly associated with disease of arteries. They found no association between small amounts of fibrosis and arterial disease. Dr. Williams said he is referring to a small point of fibrosis in a papillary muscle. To call this an infarct is, I think, misusing the English language.

Dr. WILLIAMS: It depends where you draw your size difference. I agree that most of the lesions were tiny and irrelevant. This was of the order of, say, two or three mm. across.

Professor HARRISON: Oh, this is in the non-significant group.

Professor McMICHAEL: You showed us an occluded vessel, so that I think that this very small infarct is an exception to the Mitchell rule.

Dr. J. P. SHILLINGFORD: I wonder if I may throw a few spanners, too? I believe that one finds in heart failure secondary to long-standing hypertension small areas of fibrosis throughout the myocardium.

Professor HARRISON: Yes.

Dr. SHILLINGFORD: Therefore it seems that in hypertensive heart failure there is some replacement of muscle fibres by fibrous tissue. Secondly, the heart lesions could possibly have been secondary to an embolus in a small artery.

Dr. WILLIAMS: There were two occluded arteries in separate sections; they may have been the same one. There were quite

a few small plaques of atheroma without significant occlusion in the major vessel. No other small artery, in the sections I have looked at, showed this change. I don't know where on earth this hypothetical embolus is coming from.

Dr. J. G. AZZOPARDI: I think it's fair to point out that ulcerating atheroma of the coronary arteries with peripheral embolization has rarely been described. It has more often been described in the abdominal aorta, where you get it embolizing to the spleen and the kidneys. There was very little atheroma in this case.

Dr. WILLIAMS: Just a few small plaques.

Urinary Steroid Tests

Dr. L. R. I. BAKER: Could I ask Dr. Cope what his experience is of urinary steroid tests in patients who may have defective renal function.

Dr. COPE: One cannot generalize about steroid tests. Most of the ordinary tests, if they are reliable, will remain reliable in the presence of quite a big drop in renal function; down to about 40% of the normal, perhaps. But with some of these tests—and the urinary cortisol is one of the sensitive ones—renal function can fall even further below normal. Even a blood urea raised above 100 mg. can still be compatible with a well-raised cortisol in the urine.

Dr. G. F. JOPLIN: May we take up one or two of the questions which Dr. Cope raised for discussion. I think the first point that he raised was the relationship between the diabetes and the Cushing's disease in this patient. Now we have it recorded here that the diabetes came on in 1950 and she was not hypertensive until 1956. This would be a very unusual order of events in the natural history of the evolution of Cushing's disease. For a start, only a small proportion of Cushing's cases develop diabetes even in the terminal phase of the disease. One would guess, therefore, that the odds are very much that the diabetes was unrelated to the Cushing's disease. There is another point here, which often puts off physicians from making the diagnosis of Cushing's disease, in that in 1960 the menses were recorded as regular. Now this is sometimes advanced as evidence against the diagnosis of Cushing's disease; but in our own series of about 50 patients with Cushing's disease about half of the women continued to menstruate after they'd clearly developed Cushing's disease. So continuation of menstruation by no means precludes the diagnosis.

On the question of the normal basal urinary steroids in the presence of Cushing's disease: in our own series we had three or four patients who had quite obvious Cushing's disease on clinical grounds, yet repeatedly normal urinary oxogenic steroids as recorded in our own laboratory; what showed these patients as being quite abnormal was the resistance to dexamethasone suppression. I would guess that if the dexamethasone suppression tests had been employed it's quite possible that a biochemical diagnosis might have been made.

A most important aspect of this case from the endocrine point of view is the pituitary tumour. Now review of the necropsy x-rays certainly would lead us to raise no questions of pituitary tumour here. This was a very, very normal pituitary fossa radiologically, and yet there was an unequivocal early tumour, which may have been invasive. This is of considerable importance in that it has been alleged that the reasonably high incidence of pituitary tumour following adrenalectomy for Cushing's disease is a consequence of the adrenalectomy. Our own series goes right against that view, in that a fifth of all the Cushing's cases had radiological evidence of pituitary tumours even before any treatment was done. Today's case is a very important bridge case, in that it shows quite clearly that tumour formation can occur in the absence of radiological abnormality. Could I finally ask Dr. Cope a question about the terminal illness? How many milliequivalents per day of potassium was this patient being given after implantation, and was she still getting this potent diuretic combination?

Dr. COPE: No, she was not having diuretics. She was getting potassium quite definitely, 3 g. potassium chloride four-hourly, that's six times a day, 18 g., and it was stepped up intravenously later. I can't help wondering whether the rapid swings in the potassium level didn't have an adverse effect on the myocardium, and I suspect, in fact, that metabolic myocardial trouble was vastly more important than any vascular. But that's an imponderable at the moment.

Dr. SHILLINGFORD: I should have thought that with the size of the area of ischaemia this is correct. Sudden death or sudden asystole, ventricular fibrillation, or ventricular tachycardia seldom occurs in hypertension without other cause. It is frequent in disturbances of potassium and other electrolytes, and with a potassium of 2.1 mEq one would perhaps expect some sort of arrhythmia in this condition, either ventricular tachycardia or ventricular fibrillation; I suspect at the end she developed ventricular fibrillation, then asystole.

Dr. JOPLIN: Was she receiving digitalis then?

Dr. COPE: No, she wasn't.

Dr. O. WRONG: The histological changes of potassium depletion in the kidney are not very common. I know they're regarded as characteristic, but in the majority of cases I've seen with hypokalaemia, who have had biopsies or who have come to necropsy, these changes have not been present. I think these changes indicate that there must have been a very considerable potassium deficit.

Dr. COPE: I think we may well stop at this point.

We are grateful to Professor J. P. Shillingford and Dr. E. D. Williams for assistance in preparing this report, and to Mr. W. Brackenbury for the photomicrographs.

Computer Method for Deriving Hospital Inpatient Morbidity Statistics Based on the Person as the Unit

S. P. WATTS,* B.Sc. ; E. D. ACHESON,† M.A., D.M., F.R.C.P.

Brit. med. J., 1967, 4, 476-477

In a previous paper (Acheson and Barr, 1965) an account was published of the patterns of readmission from home and of transfer between hospitals for patients in the Oxford area. It was shown that within the calendar year 1962 9.5% of the patients discharged from hospital were readmitted and discharged again once or more, 4.9% were transferred once or more between hospitals, and 1.9% were readmitted and transferred.

It was also shown that for certain conditions morbidity rates calculated from discharges rather than from persons discharged were inflated to a considerable degree. The material for 1962 was based on a manual system of record linkage, and the analysis was by business machines. This paper describes a method of calculating inpatient morbidity and fatality rates by means of a computer. Each patient is counted once in any one year regardless of the number of admissions to the same or different hospitals with the same complaint.

Material and Method

The Oxford Record Linkage Study has recorded details of every birth, admission to hospital, and death occurring in the Oxford area since the beginning of 1962. Information about these events is brought together into a series of personal cumulative files. From 1963 onwards a computer system of record linkage has been employed. The basis of the system is a master file written on magnetic tape which contains the cumulative records of the persons.

Each personal file consists of identifying data, together with a record containing statistical information for each of the defined events which the person has experienced. For each new event two cards are punched; the first contains the name, date of birth, N.H.S. number (when available), and other identifying information, and the second contains statistical data. These cards are read into the computer, where they are edited and then written on magnetic tape. The data on this magnetic tape are sorted into a sequence based on soundex code of surname, sex, and initial of first forename. The identifying information on each new record is compared with the corresponding information on all records on the master file, which fall into the same soundex-sex-initial pocket. If a linkage is obtained the new statistical record is added to the person's file; if no linkage is obtained a new personal file is created. The computer used for this operation was an IBM 1401 with 16,000 characters of core store and six magnetic tape-decks.

The linked file for 1963-4 was scanned for all persons who had been discharged from hospital once or more. A new item was formed from the existing record for each episode of inpatient treatment and written on another magnetic tape. The following information was contained in the new item:

Personal identifying number, sex, age, and place of residence.
Diagnosis on discharge (four-digit code from *International Classification of Diseases*).

Month and year of discharge.

Source of admission.

Disposal, including whether living or dead on discharge from hospital.

Hospital.

Duration of stay in hospital.

Markers to denote the birth of a baby (in the case of women) or death in that year anywhere within the area, together with the month of the event.

Information concerning the delivery of a baby and death was abstracted from the relevant records in the cumulative personal file. A distinction between deaths in hospital and elsewhere was maintained.

The data on the magnetic tape were sorted into diagnostic order and by personal number within each diagnosis. From

FIG. 1.—Morbidity analysis listing for 1963 in Oxford Record Linkage Study area (excluding Oxford C.B.C.).

* Computer scientist.

† May Reader in Medicine.

The Oxford Record Linkage Study, Nuffield Department of Clinical Medicine, University of Oxford.

this sorted tape two forms of output information were produced: (1) a list, in diagnostic order, giving certain data about each person discharged from hospital with that diagnosis (see Fig.); and (2) a table, in the same sequence, giving numbers of hospital discharges, of persons discharged, and of deaths in hospital from which hospital morbidity and fatality rates were calculated (see Table).

Results

The section of the list dealing with diagnostic rubrics 325 and 326 (mental deficiency and other disorders of character) is shown in the Fig. Separate lists were produced for 1963 and 1964 and for the Oxford county borough and Oxfordshire. In addition to denoting the personal number, diagnosis, age, and sex of each patient, the list indicates the fact of death if this occurred anywhere in the area in that year, whether

will shortly give place to the Hospital Activity Analysis, which entails the collection of abstracts for all spells of treatment (Benjamin, 1965). A conservative estimate of the cost of processing data on the recommended scale for the 4,900,000 episodes of inpatient treatment carried out in England and Wales in 1966 would be £1m.

This paper describes a computer system which eliminates two of the errors inherent in morbidity statistics published by the Hospital In-patient Enquiry—namely, the inflation of morbidity rates and the underestimation of hospital fatality rates. Both these errors stem from a single cause—namely that, as the abstracts are not identifiable, patients admitted more than once for the same condition are counted more than once in the tables. The Hospital Activity Analysis, in the form in which it is at present being implemented, will also be liable to these errors because the only identification data which is

Table of Discharge and Fatality Rates

at home or in hospital, by means of an asterisk. Delivery of a baby to females within the year is indicated by the numeral "1." Confidentiality is maintained, since no names appear on the list and the personal number which is listed has no meaning outside the computer system.

The Table shows part of the systematic tabulation which was produced. The columns from left to right give the number of discharges, the number of persons discharged once or more, and the number of deaths in hospital, together with the uncorrected and corrected discharge and fatality rates. The column on the extreme right is the factor (expressed as percentage) by which each uncorrected morbidity rate is inflated and each uncorrected fatality rate reduced on account of readmissions of the same patient for the same condition. The figures for carcinoma of the cervix illustrate an extreme instance of the inaccuracy which may occur when the number of discharges is used as the basis for calculation of morbidity and fatality rates.

Discussion

In spite of their incompleteness, statistics derived from records of spells of inpatient treatment in hospital are likely to continue for many years to be the principal source of morbidity data available on a national scale. The problems of adding data from outpatients and from episodes of domiciliary care to the material are formidable, and routine analysis of these categories of sickness are unlikely to be seen on a national scale in the near future.

It is therefore important to make the best use of the material which is likely to be available in the short term. The Hospital In-Patient Enquiry which was set up after the war (Ministry of Health and General Register Office, 1959 *et seq.*), and which required the collection and analysis of data about every tenth spell of inpatient treatment throughout England and Wales,

scheduled for processing is the filing number of the hospital or department concerned.

A further penalty of failure to include adequate identification data in the part of the abstract which is processed is that it is impossible to collate data of the subsequent fate of patients in other hospitals or elsewhere to the abstract in hand, or to relate the abstract to the previous history. At present, information about the fate of patients after discharge from hospital is defective (Hubbard and Acheson, 1967). In terms of the flow of medical information each hospital or hospital group is thus isolated in the Hospital Activity Analysis from all others and from the other branches of the Health Service (Acheson, 1967).

Summary

A computer method is described whereby hospital inpatient statistics may be derived in which the person rather than the discharge is the unit. The key to such a system is the provision of adequate data about the identity of the person treated. Results are presented which measure for selected conditions the magnitude of the errors introduced by counting, as is the practice in conventional statistics, the same person who is readmitted for the same condition more than once.

The Oxford Record Linkage Study has derived financial support from the Nuffield Foundation, Ministry of Health, and the Nuffield Provincial Hospitals Trust. It also obtains valuable assistance from the General Register Office.

CONFERENCES AND MEETINGS

Allergology

[FROM A SPECIAL CORRESPONDENT]

The Sixth International Congress of Allergology was held in Montreal from 5 to 10 November, under the presidency of Dr. BRAM ROSE (Montreal).

The first major symposium dealt with the cells which are now regarded as the hall-marks of immune processes. J. F. A. P. MILLER (Melbourne) outlined the evolution of the progenitor stem cell from its origin in bone marrow to its final sophisticated role as an antibody-forming cell in the lymph node, via thymus lymphocyte and the circulating pool of long-living antigen-reactive and antibody-forming cells. It was possible that the simple progenitor cells were passive receptors of information, but it was still conjectural where the transfer of information took place.

G. MACKANESS (Saranac Lake) described how mononuclear phagocytes or macrophages engulfed antigenic material by pinocytosis into its pinocytic vesicles or pinosomes, and then transferred it to lysosomes. These organized packages of enzymes then degraded antigen into its constituent nucleic acids, though the fate of the latter was not clear. Anti-lymphocytic calf serum had been found to stimulate pinocytosis of macrophages and it helped to destroy antigenicity. Irradiation did likewise by causing cell lysis, and thereby the production of nucleic acid derivatives, which were powerful promoters of endocytic activity in macrophages and degradation of antigen and antigenicity. This might explain the immunosuppressive effect of irradiation in delayed-type hypersensitivity reactions and in graft reactions, in which mononuclear phagocytes had such a conspicuous role.

M. LITT (Boston) had studied the effect of inoculating the footpad of the guinea-pig with haemocyanin or chick erythrocytes, which produced eosinophils in the draining lymph nodes within minutes. This reaction was suppressed by cyclophosphamide. He felt that the prime excitant of tissue eosinophilia was an antigen-antibody complex. The eosinophilotactic property of serum, which was responsible for the activity of eosinophils, was due to a gammaglobulin.

Transplantation

Pointing out that homograft rejection followed the intimate admixture of the graft antigen with sensitized lymphocytes, R. BILLINGHAM (Philadelphia) felt that some other pharmacological factor also contributed. This lymph-node plasma factor appeared early and governed migration of macrophages; it was possibly a protein or a nucleic acid.

During the last four years Montreal's McGill University had transplanted cadaver kidneys to 79 patients with renal failure, most of whom were under 45 years old. The preparatory immunosuppressive regimen to overcome homograft rejection included local irradiation, oral corticosteroids, azathioprine, and actinomycin. Complications immediately

after operation comprised rejection, acute tubular necrosis, and vascular upsets. Immediate rejection, seen especially in multiparous women, was related to lymphotoxicity to their husbands' antigens. Other rejection processes in the first two months post-operatively developed more insidiously, with gradual progressive deterioration of renal function. Finally, sequelae attributable to prednisolone included infections, aseptic necrosis of the head of the femur, pancreatitis, and bowel perforation. In his detailed review of this considerable experience J. DOSSETOR (Montreal) pointed out that previous sensitization by haemodialysis was not deleterious to subsequent renal transplantation; in fact the opposite seemed to be the case in practice. The two-year survival rate was 40%; he felt that he could generalize that the patient who was alive at six months would also be alive at two years.

T. STARZL (Denver) emphasized the immunosuppressive value of antilymphocyte serum prepared by the subcutaneous injection of human spleen into horses. The harvested antilymphocyte serum, which was a gammaglobulin, was then inoculated intramuscularly into renal graft recipients, daily at first and then twice weekly. It behaved synergistically with oral corticosteroids and azathioprine, so that the dose of prednisone and azathioprine could be halved. Whereas there had been a survival rate of about 50% before the availability of antilymphocyte globulin, only 1 out of 20 patients had died since its introduction 17 months ago. Moreover, before July 1967 all seven patients who had received liver homotransplants had died. Since then, however, with the help of antilymphocytic globulin, three out of four patients had survived more than two months. Another advance had been the preservation of donor livers for up to 24 hours by the use of hyperbaric oxygen and hypothermia.

Since antilymphocyte globulin was a protein, it was not without its risks, which included serum sickness, anaphylactic reactions, fever, and pain at the site of injection—but so far serum-sickness nephritis had not complicated 2,500 injections in 60 patients.

Sarcoidosis

EDITH MANKIEWICZ (Montreal) reported the frequent isolation of mycobacteria and their phages from the serum and specimens resected from patients with sarcoidosis. Serum antibodies to these mycobacteriophages were readily demonstrated in patients with active tuberculosis but not in sarcoidosis patients. She claimed that the absence of antibody to mycobacteriophage was responsible for the lack of caseation and the inability to find tissue mycobacteria readily.

D. GERAINT JAMES (London) said that the cardinal feature of depression of delayed-type hypersensitivity was presumably due

to immunological bankruptcy of thymus-mediated lymphocytes. Whereas there was hyporeactivity of these antibody-carrying lymphocytes, circulating or serological antibodies were unimpaired. The other characteristic feature of sarcoidosis was the formation of torpid granulomas in all tissues, and also in response to the intradermal inoculation of human spleen sarcoid tissue.

D. G. WRAITH and K. MAUNSELL (London) reported that a mite, *Dermatophagoides*, found in house dust, was an important and widespread cause of respiratory allergy in Britain. High concentrations of the mite were noted in bed mattresses of all types, particularly if they were not regularly brushed and aired, and also in bedroom floor dust, socks, handkerchiefs, and pockets. Intradermal skin tests with mite extracts were positive in dilutions up to 1 in 10,000,000.

A. W. FRANKLAND (London) also drew attention to insect allergens which could be inhaled or injected by stings. Man responded to mosquito bites by the development of delayed-type and immediate-type reactions, both of which disappeared with desensitization. Locusts were strong sensitizers causing asthma, particularly in those who were constitutionally susceptible. He also warned of the dangers of the grain weevil in wheat causing baker's asthma, and of bee stings causing acute anaphylaxis and sudden death—especially in those who had been sensitized by previous stings.

Asthma

A. W. FRANKLAND (London) also reviewed the many factors responsible for asthma. Although asthma was influenced by corticosteroids, allergic asthma was often unimproved during pregnancy. He reiterated the possible danger of cardiac arrhythmias and even sudden death due to the abuse of atomizers containing adrenaline.

The potency of these bronchodilators was emphasized by D. BATES (Montreal), for airways obstruction was reversed and the forced expiratory volume improved within two breaths and was maximal within 20 minutes of using an aerosol. Relief of spasm of the bronchial musculature seemed too naive an explanation for such rapid reversibility. ¹³¹I administered by inhalation and intravenous radioactive xenon were now being applied to the study of respiratory function in asthma, and he paid tribute to important observations made by Dr. Wilcox at Sydney University with these techniques. Ventilation was noted to be poor in the apices and bases of the lungs of asthmatics, whereas the maximal abnormality was only at the lung bases of the chronic bronchitic smoker. Bad zones of ventilation revealed arterial oxygen tensions as low as 50 mm. mercury. Scans showed uneven distribution, and the asthmatic lung adjusted its perfusion to the abnormal ventilation. From measurements of the gradient

between mouth and oesophageal or pleural pressure the overinflated lungs of asthmatics seemed to lose their elasticity temporarily. He also drew attention to the syndrome in which bronchospasm did not coincide with exercise but instead developed when the subject was resting four minutes or so after exercise. He wondered whether metabolic acidosis led to a falling pH, which had a spastic effect on the pulmonary circulation. The post-exercise bronchospasm diminished or disappeared with adrenaline or its analogues.

Systemic Lupus Erythematosus

Using the immunofluorescent technique to demonstrate circulating antinuclear antibodies in systemic lupus erythematosus, J. T. WATSON and his colleagues (Montreal) had defined four patterns of nuclear fluorescent staining—homogeneous, mixed, composite, and peripheral. These patterns had correlated with the level of serum complement and with clinical severity of the disease. The homogeneous pattern was associated with inactive forms of disease; the peripheral pattern with the most

acute forms of disease; and a shift from homogeneous to peripheral pattern heralded an exacerbation of clinical activity and a fall in the serum-complement level. This change from homogeneous to peripheral seemed to occur stepwise, the first change being from homogeneous to mixed pattern, then from mixed to composite, and finally from composite to peripheral. Whereas this indicated a poor prognosis, the reverse sequence occurred with adequate immunosuppression. They felt that changes in pattern of this nature were useful in anticipating clinical exacerbation and in assessing the adequacy of therapy.

J. H. VAUGHAN (Rochester) reported a series of 15 patients in whom the syndrome was provoked by procainamide. Symptoms usually began after the drug had been taken for several months, but had occurred following only a fortnight's administration. Eight months after discontinuing the drug most of the patients were asymptomatic, the gamma-globulin level had fallen to normal, the Coombs test was negative, and antinuclear antibodies had disappeared from the sera of 4 of the 15 patients. This improvement upon withdrawal of the drug was one of the distinguishing features from the idiopathic disease, the others being absence of renal

involvement and normal serum-complement levels.

Cancer

S. O. FREEDMAN (Montreal) had prepared a tumour antigen from carcinoma of the human colon, and, by inoculating it into rabbits, produced a specific antiserum. Similar antigens could be made from embryonic gut, so that they were collectively referred to as carcinoembryonic antigen. A serological survey had shown that the specific circulating antibody was always absent in normal people. It was, however, present in 70% of patients with carcinomas of the alimentary tract, but absent in those with metastases—possibly because circulating antibodies were absorbed by such a large antigenic mass of cancer. Circulating antibody was sufficiently specific that it was absent in patients with tumours other than of the digestive tract, but it was always present in pregnancy because of the presence of foetal material. Another extension of this study was the ability to demonstrate fluorescence in antigen-antibody complexes in human rectal cancer. Thus by this method it should be possible to stain faeces for the presence of tumour antigen.

Television in Medical Education

[FROM A SPECIAL CORRESPONDENT]

The role of television in medical education was discussed by Professor I. R. MERRILL, of the Communications Office for Research and Teaching of the University of California, at a lecture at B.M.A. House on 16 November, with the President of the B.M.A., Mr. R. V. COOKE, in the chair.

Professor MERRILL said that it was an exciting time in the development of medical television, as financial support was now being provided for it. Television was an electronic device capable of providing either entertainment or instruction. In his view this latter role was of great benefit in medicine provided television was used with discrimination. While the process was expensive, and the value of simpler visual aids such as the slide projector should not be forgotten, there were at least five properties of television which enabled it to provide an outstanding service. Firstly, image multiplication allowed the popular lecturer or an intricate surgical operation to be seen by many audiences simultaneously. The second property, of image magnification, was the television camera's ability to present minute detail. Thirdly, image association was often of great advantage in teaching—for example, by using superimposed electrocardiographic records in the same picture as the diseased heart to which they referred. Fourthly, image transportation allowed large numbers of viewers into a sterile operating-theatre or a cramped pathology laboratory. Finally, image memory, in the form of videotape and kine-scope recording, was of obvious value for future reference.

Continuing, Professor Merrill said that he was convinced that the use of television was now established in America. Already half

the existing medical schools used it and all the future ones had plans to incorporate it in their development programmes. The growth of the use of television in San Francisco, in particular, was shown by the increase in the number of presentations—from 60 in 1960 to 585 in 1966. He thought that it was vital that medical schools be given priority for television over other university departments as the money became available. The study of medicine was much concerned with the demonstration of tissues and of practical procedures, which were all particularly well displayed on television. Nevertheless, medical teachers would do well to beware of television's deadly friends. These included the obsessive innovators (though luckily these were now mainly occupied with computers); the unscrupulous salesmen, milking the ready funds with inadequate equipment; and the faculty members who shelved the apparatus after an inadequate trial.

Postgraduate Education

Professor Merrill emphasized that the education of the postgraduate should not be forgotten. Television broadcasts to general practitioners would help them in the continual betterment of their practice, and he cited the work of A.S.M.E. and the B.B.C. and I.T.V. Medical teachers could be greatly helped by the professional television producer, but the former must be clear themselves about the aim of the programmes. Unfortunately, at present there was no useful measure of the effectiveness of television in postgraduate education, and this was not possible until the aims had been accurately defined.

Opening the discussion, with LORD COHEN OF BIRKENHEAD in the chair, Dr. CHARLES FLETCHER spoke of the broadcasts aimed at the general practitioners at home. There was a difficulty in gauging the response owing to the lack of feedback. Programmes could be shown only at "off peak" times for minority viewers. It was known in the early days of the television programmes, which had been limited to the London area, that the viewing doctors numbered 35% of the maximum possible. With expansion of the service it was more difficult to measure this figure, but he thought it was about 10%. Their aim was set at the illumination of the subject rather than at the acquisition of facts, which were much more difficult to put over satisfactorily.

Professor ROGER WARWICK (Guy's Hospital Medical School) spoke of his use of television in the context of image magnification. He considered that colour was called for only in a minority of situations. Replying to a question about whether there were any methods of testing the efficacy of television as a teaching aid, Professor MERRILL said that attempts were being made by examining patients' hospital records and the prescribing patterns in small communities following programmes. To another question, he said that three hours out of every 100 total teaching time was probably the optimum amount, while the upper limit would be five.

One speaker wondered whether the medical broadcasts might be dangerous for the lay public. He had heard of complaints from practitioners about the increase in hypochondria following these programmes. Dr. FLETCHER replied that the B.B.C. had esti-

mated their lay audience at about half a million. They had received only a handful of letters on the subject, and the overall impression from laymen was one of boredom.

Professor MERRILL was asked about the place of cinematography. He thought that there was still a place for both film and television. The former had certain advantages as regards definition, contrast, and colour reproduction, and also if the presentation was to be repeated many times or in places where only cinema projectors were available. On the other hand, television recordings were easier and more rapid to make and were immediately available for editing and show-

ing. This was a further advantage for teachers who wished to improve their lecturing technique. The rehearsal of lectures could lead to greater conciseness and effectiveness.

Another questioner spoke of televised anatomy demonstrations in Dublin in 1956 by Professor A. K. Henry, and pointed out that the ability to show in rapid sequence cadaver, diagrams, and preserved specimens made the use of television particularly effective in this subject. He asked whether the use of colour would be an asset. Professor WARWICK replied that in his experience monochrome was sufficient for 70% of demonstrations. Professor MERRILL added

that in America anatomy demonstrations on closed-circuit television were second in number only to those in pathology. Nevertheless, he felt that colour had the advantage of giving a sense of depth lacking in black-and-white.

Dr. ROGER MEYRICK (London) suggested that general practitioners might benefit more from watching a programme in a discussion group with a leader. Professor MERRILL replied that his work had been essentially with undergraduates, but that it was evident that an experienced teacher was more valuable than a complete range of expensive equipment.

NEW APPLIANCES

High Femoral Osteotomy with New Compression Plate

Mr. L. C. L. GONET, consultant orthopaedic surgeon, Putney Hospital, London S.W.15, writes: High femoral osteotomy is a well-established method in the treatment of osteoarthritis of the hip joint and sometimes for subcapital fractures of the neck of the femur. In the United Kingdom McMurray's osteotomy is commonly used for the abduction or valgus type, while on the Continent the name of Pauwels is associated with the adduction or varus procedure. In recent years compression fixation at the osteotomy site by one or other of these methods has found increasing favour. The two fragments are held more firmly together, thereby diminishing postoperative pain, allowing very early mobilization and weight-bearing, and thus reducing possible postoperative complications.

A compression plate should not only provide adequate compression and fixation between the two fragments, at least until the patient is weight-bearing, but should not be so rigid as to prevent the proper "bedding down" at the osteotomy site—for it is here that union occurs—nor so rigid as to hold the two fragments apart. It should not interfere with the reversal of the osteoarthritic process following osteotomy, but above all it should also be simple to insert with the minimum number of instruments, be cheap to produce, make x-ray control unnecessary, and its application should come within the scope of any surgeon, for only then can it be considered for universal application.

The purpose of this paper is to describe a new type of compression fixation plate which, I believe, not only meets with the above requirements but introduces a new principle in bone fixation. It has been successfully used in 69 cases, the results of which are discussed below.

Description.—The plate (Fig. 1) is a straight spline of one piece consisting of an arrowhead with a cutting edge and a flat

base, a rounded nail portion, and a flat plate with a compression screw at the end, similar to that used in the Danis principle. The plate is made in three sizes to allow for latitude in the site of osteotomy.

Technique.—The osteotomy is performed at or above the lesser trochanter in the usual way, with or without x-ray control, and the lower fragment displaced medially just enough to allow the entrance of the arrow head. The plate on its introducer is then inserted up the medullary cavity of the proximal fragment in an inward and upward direction and at right angles to the shaft and hammered through the cortex of the upper femoral neck in the region of the digital fossa (Fig. 2). The plate on the introducer is then rotated through 90° and pulled down, when it will be felt to lock over the femoral neck and the plate will fit parallel with the shaft of the femur (Fig. 3). A transverse screw is inserted through the femoral shaft at the lowest slot in the plate and the compression screw is then turned clockwise (Fig. 4). Eight to ten full turns are enough to provide a compression force of from 45 to 50 lb.

FIG. 1.—Picture of the plate in two views.

FIG. 2.—Diagrammatic representation of plate at right angles to the shaft.

FIG. 3.—Diagrammatic representation of plate rotated through 90°. Compression not yet applied.

(20 to 23 kg.) as estimated in the Department of Clinical Measurement, Westminster Hospital, London. Three further transverse screws complete the fixation (Fig. 5). Tests carried out in the Department of Biomechanics at the Imperial College of Science and Technology, London, have confirmed the linear strength of the plate in conditions resembling surgery. The introducer and spanner are the only other instruments required.

Preoperative and Postoperative Treatment.

—All patients are given preoperative crutch-training to gain confidence for what would be expected after the operation, and the post-operative plan is explained to them. A plaster boot with an outrigger is applied after operation to prevent external rotation for the first two days, and is bivalved the next day to allow for attention to the heel. It is then

FIG. 4.—Diagrammatic representation of plate with compression applied.

applied only when the patient is in bed at night for the first five days. The patient sits out on the second day, and is allowed partial weight-bearing on crutches on the third day, going on rapidly to sticks, depending on the age and ability of the individual. Most patients by three to four weeks are self-supporting and can go up stairs.

RESULTS

Sixty-nine osteotomies have been performed. The criterion of assessment from excellent to good is based on the degree of reduction in pain and improvement in function, movement, and contracture (Van Nes, 1961). Three had had bilateral osteotomies from six weeks to 18 months after the first. Three patients have died from causes associated with their ages—79, 84, and 85 respectively. The results in nine patients between the ages of 47 and 60 can be regarded as

excellent. The older age group from 61 to 87 had gross osteoarthritis of one or both hips. All these have been greatly improved with regard to both loss of pain and increased mobility. Even in gross cases the reversal of the osteoarthritic process could be seen radiologically. In one patient the compression-screw became detached 15 months later,

FIG. 5.—X-ray film showing anteroposterior view of completed compression plate fixation after 18 months.

but union was solid and the loose screw was easily removed. Three cases in this series showed a slight varus bend in the nail from 5 to 15°, but union was sound. In one case of a colleague, in which there were severe postoperative convulsions, the nail was bent to 60° and was later removed.

Nevertheless the overall figure of 93% excellent-to-good results compares favourably with Nissen's (1963) figures and those for Batchelor's (1963, 1966) varus osteotomy. Thus this operation almost guarantees improvement at the very least, a consideration which is often unappreciated by general practitioners, who should be made more aware of its benefits even in the chronic and very elderly.

DISCUSSION

The very early weight-bearing is in itself a help towards compression and bedding-down at the osteotomy site as the preloading compression force diminishes. Radiological union is often seen in four weeks. In some cases x-ray films four weeks to 22 months after operation show that the arrowhead has risen slightly above the femoral neck, and

in two cases quite appreciably. Thus the possibility of cutting downwards is remote. It also demonstrates that the plate does not tend to hold the fragments apart, nor does it produce a valgus tilt. In fact a varus result predominates in this series, and this can be achieved by design at operation when it is more advantageous to centre the head of the femur in the acetabulum.

The upper part of the femoral neck has a good hard cortex, which slopes posteriorly. Penetration and locking of the arrowhead can therefore occur "high" or "low." An upward slant on introduction of the plate ensures a high position. In every new method attention to small details in operative technique is important if one hopes to attain the same results.

Rotation of the plate through 90° with a locking effect opens up a new technique, which can be applied to other procedures such as arthrodesis of the hip joint and compression fixation of oblique fractures of the long bones.

Subcapital Fractures of the Femoral Neck.—Two cases of old ununited subcapital fractures of the neck of the femur have been successfully treated by osteotomy after reduction and the use of this compression plate. One fresh subcapital fracture can be classed as an excellent result, and another as a good result so far. In those cases, however, while the patient can be got up on crutches, weight-bearing is delayed for four to six weeks unless a weight-relieving calliper is fitted.

No one method of carrying out compression osteotomy is wholly better than the other, but surgeons should have the choice of alternative procedures.

"There are many roads that lead to Rome."

I acknowledge with grateful thanks the help of Mr. I. McLeod-Balkie, of Epsom District Hospital, for allowing me to review his many cases, and other orthopaedic colleagues; the Department of Clinical Measurement, Westminster Hospital; the Department of Biomechanics at the Imperial College of Science and Technology, London; the London Splint Company, who developed the plate; and Smith Kline and French for a colour film of the technique at operation.

Letters to the Editor should not exceed 500 words.

Hospital Boards

SIR,—The Minister of Health has recently said that he proposes to overhaul the administrative machinery of the Health Service, and hints have been dropped that area control may well emerge as the effective pattern. Devolution to areas (rather than to regions), each responsible to the Ministry, must surely be a welcome idea in the hospital world at least.

It is no secret that, arising out of the establishment of a teaching hospital at Nottingham—that is, in a regional board's sphere of influence—a strong move is being made in certain quarters to alter completely the composition of the boards of governors of the teaching hospitals of England and Wales and possibly to bring these hospitals under the regional boards, as in Scotland. A second, and separate, issue is to increase the influence of the universities upon the administration of the teaching hospitals within which the university teachers and researchers work. Attempts are being made to integrate these two issues, and it is very important that the medical and lay staffs of the teaching hospitals should consider their own attitudes to possible changes, and to be vocal about them if necessary. The Goodenough,¹ Guillebaud,² and Porritt³ Committees have all affirmed that the teaching hospitals of England and Wales should continue to be independent of the regional boards, and recent meetings of the Teaching Hospitals' Association and of the deans of the medical schools of the English universities have said the same thing.

Taking regional boards first, one must hark back to the Health Act of 1948. In Scotland (as mentioned) the teaching hospitals have always been under the regions, and they never have had direct access to the Department of Health for Scotland. There is an almost 50-50 division of opinion in Scotland about whether this has been a good or a bad thing. Certainly the Scottish teaching hospitals started as being the favourite children of the boards, but the interposition of a board between themselves and the Department of Health has proved irksome, frustrating, and productive of delay. In England and Wales the regional boards have gradually obtained more and more power than was overtly stated in the terms of the Act—by reason of their control of finance and the appointment of consultants—and have consistently ridden roughshod over the local hospital management committees in such matters as hospital planning. Meanwhile the regions have set up imposing headquarters buildings at the taxpayers' expense, all full of administrative persons busily fulfilling Parkinson's Law. In this set-up they have always been irked by and jealous of the board of governors, and the direct access which these enjoy to the Ministry of Health. It is small wonder that they have cast covetous eyes on the teaching hospitals and that

they now possibly welcome the universities as potential allies.

Hospital consultants and administrators should consider very seriously whether in their view it would not be in the best interests of the service—and therefore of the patients—if the regional boards ceased to exist as anything but advisory bodies, rather than that they should swallow the teaching hospital boards. I believe that the Guillebaud Committee rejected this idea, but this was at a time when a situation of global war (with its inevitable regionalization) was rather more thinkable than it is now, and I submit it is a possibility which should once more be considered seriously. I can see no reason at all, for example, why any of the areas at present working through the Oxford Regional Board should not be given an area board of governors having as direct dealings with the Ministry as does the board of governors of the teaching hospital. It is argued against this sort of arrangement that it would mean greatly increasing the staff at the Elephant and Castle. Since the work of the Ministry staff turns preponderantly upon finance, a top-heavy increase of staff at that level could be avoided by giving all boards of governors a block grant of money for their year and letting them spend it to best advantage; such an arrangement might even lead to a diminution of administrative staff centrally. The present Government apparently favours decentralization of many services. Here would be an opportunity for just that.

Now one comes to consider the existing composition of boards of governors of teaching hospitals. These are made up of persons of integrity who voluntarily give their time to what is often a difficult and largely unrecognized voluntary service. The Minister has the final voice in appointing the persons forming the boards, but the universities nominate one-fifth, the medical staffs one-fifth, the regional boards one-fifth, and the Minister personally appoints two-fifths after consultation with local interests. The universities feel that they are under-represented, and I think this is so. The consultant staffs feel that they, too, are under-represented, and I believe this also to be true. Neither university nor medical nominees, however, are necessarily good business men, and it would be vital to retain the help of lawyers, bankers, and men of affairs. My suggestion for a reconstitution of teaching hospital boards of governors would be university one-third, medical staff one-third, and other persons one-third. This last category would in fact be a fusion of the three-fifths at present forming those representing the regions and the direct nominees of the Minister. In other words the influence of those who know about teaching and patients would be increased and that of politics would be diminished. This would do nothing but good. If in such reconstitution it was thought that larger boards

were needed this would be acceptable and they could act through a smaller general purposes committee, as is the habit in the regions at present.

At a time when medical education is under scrutiny it is vital that the medical schools of the universities obtain better facilities than they enjoy at present, and one way of securing these is to have a bigger representation on hospital boards; but the part-time teachers who make up the consultant service on the one hand and do most of the teaching on the other must keep a watchful eye upon the possible outcome of a potential alliance between the universities and the regions, which is unexpected and could be dangerous.—I am, etc.,

Radcliffe Infirmary,
Oxford.

Varicose Ulcers and Use of Topical Corticosteroids

SIR,—The object of this letter is to draw attention to the harmful effects which may occur from the use of corticosteroid ointments and creams on stasis or varicose ulcers. We are seeing more and more patients in whom the application of these preparations to this type of ulcer has led to its rapid extension in diameter and depth, often with severe secondary infection from *Ps. pyocyaneus*.

In our opinion it is quite wrong to use corticosteroids on these leg ulcers, and antibiotic or bactericidal substances added to them are inadequate to control secondary infection. It is true, however, that topical corticosteroids are valuable in the treatment of stasis eczema, provided that it is possible to avoid contamination of the ulcerated area by careful application, detailed instruction, or demonstration. Also, as the starting points of these ulcers or recurrences may be scratches on such an area of eczema, the use of corticosteroids on residual eczema may be justified. However, in such cases, after abrasion occurs and becomes secondarily infected, the continued use of the application may favour extension. The newer and more powerful corticosteroids will have a greater effect in this connexion, and sprays containing corticosteroids are unlikely to be used without contaminating the ulcerated area.

In our opinion the use of topical corticosteroids on leg ulcers is never justified, whether in combination with other preparations or not. If they are used on associated eczema they must be applied with the greatest care and must not be allowed to contaminate any ulcerated area.—We are, etc.,

Computers in Medicine

SIR,—Your leader on computers in medicine (4 November, p. 250) was timely, and you so rightly pointed out that "the most powerful computer can originate nothing." So much in clinical medicine in the past has been padded with waffle, and in the computer age there will be no room for it. Already I have heard of examples where clinicians were unable to communicate fully with programmers. Many doctors will have to learn basic computer systems, and yet already I have experienced confusion in this field.

I recently attended the three-day introductory course at Elliott Medical Automation, University College Hospital. The lectures on the second and third day of this course were on A.L.G.O.L. programming, which is used by Elliott-Automation Computers Ltd. Two of the doctors on the course were medical officers of health and their authority had installed a Honeywell computer, which used C.O.B.O.L. language. For my own research I have been offered facilities on an I.B.M. 1401 which uses C.O.B.O.L., but part of my research involves the use of a psychiatric inventory which has a prepared programme written in F.O.R.T.R.A.N. (the I.B.M. computer language). Fortunately for me I.B.M. have gone out of their way to help me and I have no problems.

However, I do feel that there should be some rationalization in the medical computer field. We do not wish to be told what computers we should use, but I wonder whether it would be possible for the B.M.J. to run periodically a summary of what is happening in the medical computer field.—I am, etc.,

Hinckley, Leics.

PETER A. PARISH.

Cerebral Localization of Psychological Function

SIR,—May I report in the accompanying Table on three patients I have recently seen in this vicinity, all with similar psychological findings to subnormal epileptics (Dr. P. E. Sylvester and Miss E. Blundell, 4 February, p. 282), but occurring within the normal range of intellect, in adults, all with "spike and wave" E.E.G.s and abnormal personalities, but without clinical epilepsy or any previous or family history thereof.

Sex	Age	E.E.G.	Wechsler I.Q.	
			Verbal	Performance
M	17	Bilateral spike and wave during overbreathing	102	87
F	25	On photic stimulation two brief outbursts of bilaterally synchronous generalized atypical spike and wave.	85	72
M	18	Bursts of bilateral atypical spike and wave 3-5 c/s frequently throughout, usually with eyes open, and rather more frequently on photic stimulation.	96	81

These three patients' clinical personality characteristics varied from agitated labile in the first to anergic aggressive in the second and pedantic retarded in the third. All three had at one time or another in more acute exacerbations been considered borderline schizophrenics by experienced psychiatrists,

and all then responded better to phenothiazines than to anticonvulsants, on which none was kept very long.

Each patient was tested by a different senior psychologist, and the second patient's findings were essentially the same on repeat testing at an interval of six weeks, so that the results are considered reliable. The psychological finding of a significantly higher verbal than performance score was said by the psychologist testing the first and third patients to be a sign of emotional disturbance, and in the first more specifically of schizophrenic disorder, although in my experience schizophrenic disturbance, when predominantly of language function, produces the opposite test result.

While there may well be a connexion in all this between schizophrenia and the schizophrenic-like psychoses of epilepsy, the relationship of the psychological findings would seem to require further interpretation and discussion in the light of the pathological and electrical ones. Thus the E.E.G. abnormalities in my three patients were bilaterally equal, as apparently were the smallness in linear dimensions of the parietal lobes in Dr. Sylvester and Miss Blundell's epileptics, yet the psychological differences seem to suggest that the dominant cerebral hemisphere subserving language function was less affected than the non-dominant subserving spatial ability (including "performance" tests like Koh's blocks and tests with shape and pattern).

Even if bilaterally equal congenital epileptic abnormalities were invoked by way of

explanation, as interfering with clear lateralization of developing psychological function, this should affect verbal as much as performance scores. Could the observed psychological difference therefore be more an indication perhaps of global or bilateral abnormality of the sensorium, as seen in confusion or dementia? Performance tests may depend far more on "fluid" ability than "crystallized" verbal function, and thus be more affected by such intermittent generalized disorder. Unilateral localized cerebral hypogenesis might rather account for more specific psychological defects like developmental dyslexia.—I am, etc.,

Visuo-motor Disability in Schoolchildren

SIR,—In view of the authors' statement (4 November, p. 259) that "no formal neurological examination could be undertaken in the present inquiry . . ." it would be interesting to know whether an assessment of visual acuity, refractive error, binocular vision, or muscle balance was made in the experimental group, since a defect in any of these might have affected their performance.—I am, etc.,

Orpington,
Kent.

S. E. WHITE.

Respiratory Monitoring

SIR,—We read with interest the report by Dr. J. V. Farman and Mr. D. A. Juett on the use of impedance spirometry as a monitor of ventilation (7 October, p. 27).

Our own experience has been that the impedance "spirogram" is not always a

with the record shown in Fig. 2 of the communication by Dr. Farman.

On the evidence of the disparity between these traces and on similar experimental laboratory findings, we suggest that impedance spirometry in its present form should not be regarded as a reliable monitor of

Volume: Integrated signal from pneumotachograph head. Thoracic impedance trace: 2 electrode configuration, 30 Kc generator; indifferent electrode over sternum, measuring electrodes M.A.L.6th I.C.S. Catheter mount clamped at first arrow and released at second. Short partial occlusion at the "volume" large arrow.

reliable guide to ventilation in spontaneously breathing subjects. The record reproduced above was obtained from a lightly anaesthetized spontaneously breathing patient. Total obstruction of the catheter mount, as indicated by the arrows, produced little change in the impedance trace. This is in marked contrast

ventilation in the spontaneously breathing subject.—We are, etc.,

Gastritis, Aspirin, and Alcohol

SIR,—I was interested in Dr. D. N. Croft's excellent article on gastritis (21 October, p. 164), and welcome the prominence that he gives to the role of aspirin and alcohol in provoking gastritis and haematemesis. He shows that gastritis is usually self-induced. He does not, however, mention the considerable risk of gastroduodenal haemorrhage when alcohol and aspirin are taken together, the latter often at the end of a binge in an endeavour to prevent a hangover.

Some years ago I reported to the Association of Physicians of Region No. 1 the results of a small survey of every emergency medical admission with haematemesis and melaena to this hospital in 1958 and in 1960 (unpublished). In 108 cases we found that 72 had taken aspirin in some form, as far as could be ascertained, within 24 hours of the onset of bleeding. In the year 1958, of 31 male admissions 23 had taken aspirin and 16 had taken alcohol within 24 hours of the onset, and 10 had taken both. We thought that alcohol considerably increased the risk of bleeding due to aspirin, and it was significant that male admissions with haematemesis were more frequent at week-ends and during public holidays.

Incidentally, we found that at first patients often denied aspirin ingestion, until they were carefully interrogated using several of the more popular trade names. We now hand each patient a printed list of the 321 aspirin-containing preparations they would do well to avoid in future. The most confusing was undoubtedly Alka-seltzer, none of its victims being aware of the aspirin content of this well-advertised preparation, and many thinking that it was purely an alkali and therefore taking it for gastric discomfort or pain.

Further inquiry was made into the drinking habits of the ulcer patients. There were 75 males with gastroduodenal bleeding, and 48 of these were considerable drinkers, nearly always bitter beer, and consumption varied from a mere one gallon (4.5 l.) of beer per week to as much as seven gallons per week. Of these 48 individuals 32 were considered to have a duodenal ulcer, mostly confirmed or strongly suspected. These and other figures lead one to reflect that in this district regular beer drinking, especially bitter beer, over a long number of years eventually leads to duodenal ulcer, and one speculates about whether this may explain why it is that duodenal ulcer is so much more common in men than women. If this is correct the incidence of duodenal ulcer in total abstainers should be low. It seems to me that the role of alcohol in relation to gastroduodenal troubles has hitherto been underrated, and that here is a problem which merits wider attention and further study. Also the public should be warned not to take aspirin after drinking.—I am, etc.,

North Ormesby Hospital, Middlesbrough. C. E. ASTLEY.

Body Building on Drugs

SIR,—Your leading article on the use of anabolic steroids in athletic training (11 November, p. 310) in reply to Dr. D. E. Pearson's letter (11 November, p. 353) is both timely and of importance. It may, however, be of interest to you to know that this subject has already been considered at some

length by the Medical Advisory Committee to the British Olympic Association, and that they utterly condemned the use of anabolic steroids in athletic training and pointed out the possible dangers involved in taking them. A copy of this recommendation has been sent to all the governing bodies of sport in this country.

In addition to this the International Olympic Committee has issued the following statement to the National Olympic Committees of 123 countries: "The International Olympic Committee considers the use of anabolic steroids (except for medical purposes) constitutes 'doping' from the Olympic viewpoint."—I am, etc.,

Coagulation of Rubber Latex in the Stomach

SIR,—The common poisons used by agricultural workers in Ceylon attempting suicide are insecticides, which are easily available to them. Rubber latex is not considered to be a poisonous substance, and we report here a case of attempted suicide by ingestion of rubber latex. The only symptoms produced by the ingestion of rubber latex were due to the mechanical effects on the stomach of the coagulated rubber latex.^{1,2} This is an unusual foreign body in the stomach about which there have been no earlier reports in the literature.

A 49-year-old woman who works as a rubber tapper on a rubber estate was admitted to the medical ward with a history of having swallowed a cup full of fresh rubber latex. She had confessed to her daughter that she had taken the rubber latex with the intention of killing herself. She had ingested the rubber latex four hours prior to her admission to hospital. Although alert and conscious at the time she was brought to the hospital outpatients department she refused to answer any questions. Apart from slight abdominal pain, she had no other symptoms, and seemed reasonably comfortable. On examination the pulse was 90 a minute, regular, and blood pressure was 110/90 mm. Hg. An elongated sausage-shaped lump was palpated in the epigastrium. It was firm, but could be pitted on pressure. A plain x-ray of the abdomen did not reveal any abnormality.

FIG. 1.—X-ray of the abdomen taken after barium showing the filling defects in the stomach and in the second part of the duodenum.

The x-ray of the abdomen taken after giving a dilute solution of barium to swallow showed two filling defects; one corresponding with the lump felt in the abdomen in the stomach and the other due to the presence of solid latex in the second part of the duodenum (Fig. 1).

At operation the solid latex, moulded to the shape of the stomach, was removed and the gastrotomy wound closed. This solid rubber was of creamy yellow colour with the impressions of the rugae of the stomach on it (Fig. 2).

FIG. 2.—The specimen of solid rubber removed from the stomach.

When thrown on the floor it bounced like any other piece of rubber. The other latex lump was identified in the second part of the duodenum. Duodenostomy was done and the lump removed. She made an uneventful recovery. She was later seen by the psychiatrist.

Rubber latex is a milky fluid obtained by cutting the bark of the rubber tree. This latex, when coagulated, forms the solid rubber. In the rubber factories of Ceylon coagulation of rubber is obtained by adding certain chemical substances to the latex. Eight ounces (200 ml.) of 8% sodium bisulphite and 5 oz. (125 ml.) of 6% formic acid are used for 40 gallons (182 l.) of latex for it to coagulate. In this particular case the acid present in the stomach must have in some way contributed to the coagulation of the latex in the stomach.

We would like to thank Mr. M. de S. Jayasinghe, of the Photographic Department, General Hospital, Colombo, for his help with the photographs in this case.

Prevention of Rh-haemolytic Disease

SIR,—My colleagues and I were interested in Dr. Sheila Murray's letter (4 November, p. 296), and the following are the replies to her queries:

The treated and control women in the Liverpool group who had subsequently Rh-positive babies were tested for antibodies immediately after delivery of the second baby. The babies were in all cases Coombs-negative, normal, and liveborn. In the clinical trials elsewhere, all we know is that the babies were also Rh-positive, normal, and liveborn, and that no treated women have made antibody, but we do not know the precise time at which the tests were carried out.

As far as we know, the 110 women remaining in the treated group have not become pregnant

again, nor is there any record of either stillbirths or abortions, except for a single case of abortion in the controls. However, complete ascertainment is extremely difficult and there may well have been a few cases which have not been reported. Our routine procedure is to give the mother a card when she is tested for antibodies six months after the birth of her first baby, and she is told to send it to us when she becomes pregnant again. As a precaution the case sheets of the mothers are also examined at intervals in case there is any indication that the woman has become pregnant.

The number of cases in the various trials has increased considerably since I gave my lecture, and the data have been sent to Dr. Murray. Our general experience in Liverpool of the time interval between first and second pregnancies does not suggest that a particularly small percentage of the women in the trial have had second babies.

The anti-Kell experiment gave inconclusive results because of difficulties with the anti-Kell antibody.

Dr. Murray speculates that suppression of D-immunization by anti-D gammaglobulin may be accompanied by some impairment of general immunity to infection. Not only have we followed up both our volunteers and trial women and found nothing to suggest this, but the gammaglobulin we inject differs from preparations used for other purposes only in that 1/500th part is anti-D, and I cannot see that its effect on general immunity can be different from that of the more usual preparations.

We have now tested for anti-Gm antibodies 62 treated women and have found positives in four, giving an incidence of 6.3%. The controls are still being studied, but we do not think that the formation of anti-Gm antibodies is likely to be damaging, for, if it were, it would make the giving of blood transfusions a most dangerous procedure, since incompatible Gm antigens must often be injected in large quantities in transfusions of whole blood.

Although in our first experiments, in about 1960, there was enhancement of immunization by IgM, which has never been satisfactorily explained, yet since that time we had not used IgM but always IgG both in our experiments and the clinical trials.

We do not understand the relevance of Dr. Murray's questions about the "ultimate relationship of anti-Gm in rheumatoid arthritis" to our work. The four women with the anti-Gm are entirely well and there is no suggestion that they have or are developing rheumatoid arthritis. Furthermore, there is no evidence that Gm antibodies, either natural or induced by immunization, predispose to rheumatoid arthritis, and the distribution of the Gm groups is normal in patients with this disease.

While agreeing that more research is needed, the most important point to us seems to be to find the smallest effective dose, and an M.R.C. working party is organizing trials to determine this. There is some very recent evidence on the subject from New York.¹ Four groups of 10 Rh-negative men were given 10 ml. of group O Rh-positive whole blood intravenously at monthly intervals for a total of three injections. Twenty-four hours following the administration of blood three of the four groups were given 1.0 ml., 0.5 ml., or 0.25 ml. respectively of an ortho preparation containing 1,200 µg.

Group	Dose of Ortho Anti-D Gamma-globulin	Number With Anti-Rh at 9 Months	% With Antibody
I	0	6 of 10 men	60
II	1,200 µg	0 " 10 "	0
III	600 "	0 " 10 "	0
IV	300 "	0 " 10 "	0

Pollack *et al.* (1967).¹

of anti-Rh (D) antibody per ml. Blood samples were obtained thereafter at monthly intervals for nine months and examined for the presence of anti-Rh. The results are summarized in the Table.

It therefore looks as though 300 µg. of ortho anti-D (approximately the amount being used in our current 1-ml. trial) is effective in protecting against a fairly large volume of injected Rh-positive blood.

Whether the treatment is "unquestionably right for national use" is a decision for the Ministry of Health, which has set up a sub-committee of its Standing Medical Advisory Committee to consider the whole matter.—I am, etc.,

Department of Medicine,

Allergic Alveolitis

SIR,—In your leading article (16 September, p. 691) the term "extrinsic allergic alveolitis" was suggested as the appropriate general description for a group of conditions resulting from the inhalation of antigenic material and occurring in farmers, mushroom-pickers, bird-fanciers, pituitary snuff-takers, bagasse handlers, etc.

We would accept this term as appropriate if the pathology were confined to inflammatory changes in the interalveolar septa with or without an exudate into alveolar spaces, but this is not so, because at one stage a salient feature is the presence of numerous "sarcoid-like granulomata" which induced Dickie and Rankin,¹ who first described the histology in farmer's lung, to use the term "acute granulomatous interstitial pneumonitis." Another frequent feature, as indeed is pointed out in the leading article, is a bronchiolitis, the exudate of which may become organized. Further, as is to be expected in a pulmonary Arthus or Type III reaction, vasculitis occurs. Organization of the inflammatory damage often occurs in this group of diseases, leading to a chronic stage characterized by pulmonary fibrosis.

The term "extrinsic alveolitis" invites the suggestion that this fibrosis is to be compared with diffuse idiopathic fibrosing alveolitis, now apparently the term replacing idiopathic diffuse interstitial pulmonary fibrosis or "chronic Hamman-Rich disease," where the end result produces a fine interstitial fibrosis with a respiratory function profile of transfer factor defect.

In the group of diseases now under consideration, however, this is only one of the possible end-results. In many patients there is much fibrosis involving terminal conducting airways—for example, an obstructive airways disease profile is seen in about one-third of sufferers from chronic farmer's lung.² Reporting on lung-function studies in bagassosis, Weill and others³ concluded that some dyspnoeic patients in the chronic stage had obstructive airways disease which they considered was causally related to bagasse exposure.

We therefore feel that "extrinsic allergic pneumonia" is less specific and more appropriate than "extrinsic allergic alveolitis."

One of the difficulties in interpreting the published work on farmer's lung is that authors seldom make it clear whether they

are discussing the acute potentially reversible stage or the chronic stage of irreversible fibrosis. In order to obviate this situation it is suggested that the acute stage be referred to as "acute extrinsic allergic pneumonia," and the fibrotic end-result as "chronic extrinsic allergic pneumonia." The term used should describe clearly the whole clinico-pathological entity.—We are, etc.,

Demonstration Aerosol Inhalers

SIR,—Dr. A. Herxheimer (28 October, p. 236) suggested that manufacturers of pressurized aerosol preparations should provide "demonstration" inhalers so that prescribing doctors could instruct their patients more effectively.

It has been our practice to provide doctors with inert aerosol inhalers from time to time, through our representatives. Our object has been to stress the desirability of correct administration, and encourage doctors to supplement the instructions in the patient's leaflet with a practical demonstration.

As part of our current efforts to avoid misuse and abuse of pressurized aerosols, our representatives are now offering inert inhalers to all doctors on whom they call. The co-operation of all prescribers is being sought in ensuring that patients are using the right technique, and thereby obtaining maximum response from minimum dosage.—I am, etc.,

Leicestershire.

Purpura in a Patient Taking Chlordiazepoxide

SIR,—Non-thrombocytopenic purpura occurring following chlordiazepoxide (Librium) administration has been seen recently in this hospital.

The patient, a 65-year-old well-nourished Jewish woman, was investigated for a generalized purpuric rash. She had been receiving protamine zinc insulin for many years, and for at least 12 months had been receiving irregular courses of chlordiazepoxide (10 mg. twice daily) at approximately monthly intervals, each course lasting approximately a week. On admission the chlordiazepoxide was discontinued. The routine blood investigations were all normal.

The tourniquet test was positive, clot retraction was 45% (normal 48–64%), and the platelet count varied between 114,000 to 245,000/cu. mm. A peripheral blood film showed normal platelet morphology with perhaps occasional large forms. No lupus erythematosus cells were seen. The urine contained 130 mg./100 ml. protein, sugar at times, and an occasional granular cast. Serum proteins were 7.6 g./100 ml. (albumin

3.6 g./100 ml.). Protein electrophoresis showed an increase in all the globulin fractions with mild decrease of the albumin fraction.

The most likely abnormality was therefore an increase in capillary fragility, although a qualitative defect could not be outruled. The purpura gradually faded; and on discharge four weeks later the tourniquet test, though still positive, was less marked. During her hospitalization she was transferred from insulin to chlorpropamide (Diabinese) 500 mg. daily, with good control of her diabetes and no deterioration in her purpura.

She was readmitted three weeks later with right hemiparesis due to cerebral thrombosis. Chlordiazepoxide 10 mg. was given on admission. The following morning the tourniquet test was negative and the platelet count was 200,000/cu. mm. The blood urea was 44 mg./100 ml., and urinalysis showed 60 mg./100 ml. protein only. Five days after admission she was noted to be depressed, and chlordiazepoxide 10 mg. t.i.d. was prescribed. Within 48 hours the purpura reappeared and the tourniquet test was strongly positive. The platelet count was 190,000/cu. mm. The chlordiazepoxide was discontinued; the purpura gradually faded, and the tourniquet test became steadily weaker. Nine weeks later it was negative and the platelet count was 162,000/cu. mm. It was found difficult to control her diabetes with chlorpropamide and insulin therapy was recommenced, with good control and no recurrence of the purpura. She was discharged with residual hemiparesis, has remained well, and has had no further episodes of purpura.

The only reported case of purpura occurring with chlordiazepoxide administration was at a clinicopathological conference,¹ at which concurrent chloramphenicol administration was considered responsible for the purpura. Thirty-four suspected cases have been reported to the manufacturers, but no cases have been reported in the literature. It is interesting to note that the purpura did not appear when 10 mg. was administered on the evening of her second admission, and only appeared when 30 mg. per day was given later. It seems, therefore, that there is a minimum dose needed to manifest the purpura.—I am, etc.,

Salmonella in Tortoises

SIR,—I was most interested to read Dr. L. T. Newman's letter on the problem of salmonella in tortoises (4 November, p. 296). It is a well-known fact that tortoises and related terrapins are excretors and carriers of salmonellas, and, as such, are a constant hazard to their owners and handlers, in particular young children.

In 1966, in conjunction with Dr. C. D. Plows, of the Sheffield Public Health Laboratory Service, we were able to identify an Arizona strain from a case of gastroenteritis in a 3-year-old Sheffield girl. A symptomless excretor of the organism (her 5-year-old brother) was also found in the same family. The source of infection was traced to a pet terrapin—a type of small turtle (genus: *Graptemys*)—purchased by the family from a pet shop in Sheffield. Full details of this investigation are to be reported in the *Journal of Hygiene* (in press).

Terrapins, like tortoises and turtles, are excretors of both salmonellas and Arizona. If the habit of keeping terrapins as pets increases, then these small innocuous animals may well become an important source of human salmonella infection. This is especially so in young children. Terrapins are more likely to act as a source of human infection than tortoises for the following reasons: terrapins are smaller and therefore easier and more tempting for young children to handle; they are usually kept indoors and in a tank of water; it has been observed that children do play with them and are in the habit of transferring them in and out of the tank at frequent intervals. If the terrapins are excretors then the water in the tank will become infected, so increasing the possibility of spread to humans or to other pets.—I am, etc.,

WILFRID H. PARRY.

Public Health Department,

Paraquat Poisoning

SIR,—The recent report of Dr. Ch. Almog and Dr. E. Tal (16 September, p. 721) of the result of a subcutaneous injection of paraquat (Gramoxone), with the development of a right facial paresis, prompts me to record another case of facial palsy associated with Gramoxone.

This was in a male horticultural worker of 49 who presented in May this year. He had rolled a cigarette with unwashed hands after washing spray nozzles contaminated with Gramoxone. He developed a burning sensation of the tongue and examination four days later revealed nothing abnormal. Two days later, he awoke with headache and nausea, sore throat, fever, aching of the limbs, and general malaise, and by mid-afternoon had marked muscular weakness and nearly collapsed. His temperature was 101.5° F. (38.5° C). Neck stiffness was present, and there was a thin line of vesicles on the right fauces. There was a horizontal nystagmus which the patient claimed had been present for years.

He was admitted under the care of Dr. J. Campbell, and four days later developed a right lower motor neurone facial palsy with no other neurological findings. The chest, skull, and mastoid x rays were normal. The cerebral spinal fluid the day after admission showed R.B.C.s 41/cu.mm., W.B.C.s 5/cu.mm. protein 110 mg./100 ml., sugar 100 mg./100 ml. chlorides 760 mg./100 ml. A repeat lumbar puncture one week later showed R.B.C.s 8/cu. mm., W.B.C.s 39/cu.mm. neutrophils 11%, lymphocytes 89%, protein 40 mg./100 ml., chlorides 750 mg./100 ml., sugar 104 mg./100 ml; the pressure was 150 mm. with a free rise and fall. Blood count, E.S.R., blood urea, liver function tests, aspartate transaminase, and alanine transaminase were normal; the urine contained a trace of protein, many pus cells, and follow-up intravenous pyelogram suggested old right-sided pyelitis.

A follow-up chest x ray five months later showed no evidence of any active pathology in the lungs, and the heart was of normal size (Dr. Maxwell).

This sequence of contact with paraquat (Gramoxone) and facial palsy may be entirely coincidental; the minute dose of paraquat involved might suggest a hypersensitivity response in this case. It would be interesting to know of facial or other palsies occurring in others using or manufacturing paraquat.—I am, etc.,

Dereham,
Norfolk.

K. A. MOURIN.

Low Back Pain

SIR,—“Medicine Today” (11 November, p. 341) presents what is presumably a résumé of eminent authoritative exposition of the symptoms, signs, diagnosis, and treatment of this most common of complaints. Reading this, for I have not yet seen the film, it truly amazes me that these are the practices still in vogue.

What is new? What does “Medicine Today” have to offer? Let us be reasoned, and, if you like, be with it. Let us read, learn, digest, and practise, if not all, some of the teachings of Dr. James Cyriax. He after all (and a great number of his enlightened colleagues) has been thundering out for 20 years or more the signs, symptoms, and treatment of derangement of intervertebral joints (D.I.J.).

Whether you like it or not, his whole concept works—and very well at that. The problem is for the average doctor to grasp, interpret, and treat the condition.

The essence of treatment of D.I.J., no matter how severe, is immediate manipulation (apart from S.4). The acute severely immobilized patient with lumbago or sciatica is gently manipulated, not once, but daily, on alternate days, or every third day. This, together with a rigid bed, trunk extension exercises (as soon as the patient can start them), and no lumbar flexion when up and about, has been constantly found to get the patient back to work within a week or two.

Lying doggo in bed, swallowing hundreds of painkilling tablets, sweltering under a heat-tunnel, etc., is just not good enough when immediate reduction of the D.I.J. and mobilization is all that is required.—I am, etc.,

Pondwell,
Ryde, Isle of Wight.

T. HAMBLEY.

Intestinal Spirochaetosis

SIR,—Lieutenant-Colonel C. O. Burdick (11 November, p. 357) asserts that we have “misinterpreted normal intestinal microvilli cut tangentially as spirochaetes.” He presumably bases this view on the single low-powered electronmicrograph published with our paper.

We wish categorically to deny this suggestion. There can be no doubt that the condition we described (16 September, p. 718) is an infestation of the colonic mucosa by small, spiral micro-organisms. These are much larger than microvilli but smaller than bacteria. Axial filaments are clearly visible in our own material and in negatively stained preparation of the organisms prepared by Dr. J. Gordon. The organisms are motile on dark-ground microscopy.

It is of interest that this condition is quite common and can be diagnosed from routine histological preparations. The lesions must have been seen frequently by pathologists, but it seems the appearances have not been interpreted correctly in the past.—We are, etc.,

W. A. HARLAND.
F. D. LEE.

Pathology Department,
Western Infirmary,
Glasgow W.1.

SIR,—Dr. S. C. Dyke (21 October, p. 176) has referred to my work on intestinal spirochaetosis in terms which I deeply appreciate.

The reference he gave was to a précis of a lecture to the Association of Clinical Pathologists in the *Journal of Clinical Pathology*,¹ but a very much more detailed report, amply illustrated in both colour and black and white, appeared in the *British Journal of Surgery* in 1962.²—I am, etc.,

Eastbourne,
Sussex.

A. G. SHERA.

Obstetric Forceps or Vacuum Extractor?

SIR,—No doctor would wish to challenge the second sentence of the leading article on obstetric forceps or vacuum extractor (23 September, p. 753): "... the obstetrician must not only exercise his skill to deliver the baby from its obstetric dilemma but he must also protect the baby from any damage or delay caused by the operation itself." It therefore follows that, except in the very experienced hands of either a busy registrar or an active consultant, applying a vacuum extractor, either during the first stage of labour or even in the second stage where the position of the foetal skull is difficult to determine, must be considered as potentially hazardous and decidedly risky to the life or subsequent health of the foetus. Similarly there could be no objection to a widely experienced, active, and well-qualified general-practitioner obstetrician undertaking this procedure, but of course only in a specialist obstetric unit where every facility is available for readily treating any complication.

The set of the controversy "obstetric forceps or vacuum extractor" in your correspondence columns clearly takes place in the second stage of labour. Presumably no doctor disputes the vacuum extractor's place in the management of delay late in the first stage of labour, and forceps should always be banned at this time. In the second stage there are two situations where instrumental assistance is needed.

If delay occurs in the *mid-cavity* of the pelvis it is always likely that the foetal skull is in the occipitoposterior or transverse position, such a malposition as is probably the very cause of the delay. Where assistance is needed, either for delay or foetal distress, and before the instrument of choice is applied, the position of the occiput must be accurately determined—that is, if the skull and brain are to be protected from any damage. The delivery is clearly potentially difficult, so in fairness to the child (and mother) only a very experienced obstetrician should be performing. The final decision as to instrument should depend on the obstetrician's experience, enthusiasm, and considered results with its practical use. I can well understand and admire the excellent results obtained by Mr. J. A. Chalmers and others (4 November, p. 292) with the vacuum extractor, but, on the other hand, I firmly suggest that the majority of specialists, at least in this country, would prefer to use the obstetric forceps in order to achieve their best results in these obstetric situations.

A vast proportion of instrumental deliveries take place when the foetal skull has advanced beyond the mid-cavity and has now reached the *pelvic floor*; and again the indications

for their use are either foetal distress or delay in progress. It is in this group that bony disproportion is no longer a problem, and so instrumental damage to the skull and brain is unlikely, but only provided the requisite care with the application is undertaken—and this applies whatever instrument is used. It is such a case which a general-practitioner obstetrician might easily be coping with in his general-practitioner unit, and in this situation he would naturally opt for the instrument with which he is most familiar, and, perhaps even more important, the over-riding consideration he would take in making his choice would be his wish for a delivery with the least possible delay. Surely, therefore, the majority of doctors would choose the obstetric forceps, because most of us would agree with Mr. W. H. Laird (4 November, p. 292) who says: "... most obstetricians would agree that forceps delivery is preferable to vacuum extraction in cases where rapid delivery is required in the second stage of labour when foetal distress occurs with the foetal head fully engaged, because there is no doubt that the application of, and delivery with, the vacuum extractor does take longer than forceps delivery." I suggest he should continue his argument to include the potential as well as the recognized foetal distress, and, in mentioning potential foetal distress, I naturally refer to the longer second stage of labour. It is interesting that the well-known advocate of the vacuum extractor, Mr. Chalmers, also finds that forceps delivery is quicker.

I cannot agree that the vacuum extractor should be used without any anaesthetic at all, but would consider that, as with any obstetric forceps delivery, in fairness to the comfort of the patient a local anaesthetic should be administered. Only in exceptional cases would a general anaesthetic be necessary.

Finally, I could never condone the use of the vacuum extractor being applied to a foetal skull above the pelvic brim, even for a second twin.—I am, etc.,

Alcoholism

SIR,—Thirty years ago three diseases which were little understood, feared, and therefore not talked about were tuberculosis, insanity, and alcoholism. Enormous strides have been made in conquering the first two, but there still remains the same frightened silence about alcoholism, although it is much better understood by experts if not by the general practitioner like myself. I should therefore like to support Dr. A. Spencer Paterson (23 September, p. 798), when he says that the medical attitude is of paramount importance.

The National Council on Alcoholism states that out of 34 million who drink only half a million are alcoholics, and therefore we need only bother about them.¹ These figures are very misleading manifestly, for it implies that the very great numbers of heavy "respectable" drinkers who are inefficient and who cause unhappiness to their relatives are normal. No public health scheme to

combat disease has ever neglected prevention—as the National Council appears to be doing. If a man is going to fall over a cliff we grab hold of him rather than send for an ambulance to go to the foot of the cliff.

Prevention must be studied, and this means stopping not only direct advertising, which costs £23m., but also indirect advertising. It also means a fearless education of adolescents on the dangers of drink. Marty Mann's *Primer on Alcoholism*² should be compulsory reading, and there should be many more discussions in medical societies and journals.—I am, etc.,

Hypersensitivity Reactions to Phenylbutazone

SIR,—In view of the recent interest in acute leukaemia developing after phenylbutazone therapy, it seems worth while reporting two cases seen during the past 18 months, both of which developed a blood picture with features of glandular fever following phenylbutazone administration. In one of the recent reports Dr. A. Lawrence¹ described a similar case in which "many atypical mononuclears closely resembling glandular-fever cells were seen" in the blood.

A woman aged 53 suffering from rheumatoid arthritis was treated with phenylbutazone, 600 mg. daily for one week, followed by 500 mg. daily for two weeks. A generalized maculopapular rash and a sore throat then developed, and her temperature was 100–101° F. (37.8–38.3° C.). A large soft lymph gland in the left axilla was noted, but no lymphadenopathy elsewhere, and her spleen was not palpable. The results of blood counts are shown below.

Day of Illness	W.B.C. /cu. mm.	Neutrophils /cu. mm.	Eosinophils /cu. mm.	Lymphocytes /cu. mm.
3	1,700	170 (10%)	323 (19%)	1,207 (71%)
4	2,300	40 (2%)	437 (19%)	1,817 (79%)
6	7,000	0	1,120 (16%)	5,880 (84%)
9	8,000	640 (8%)	2,960 (37%)	3,760 (47%)
11	8,000	1,840 (23%)	2,720 (34%)	2,960 (37%)
13	11,000	5,940 (54%)	2,200 (20%)	2,420 (22%)
17	8,000	4,720 (59%)	480 (6%)	2,480 (31%)

On days 3 and 4 a few of the lymphocytes were atypical, and some of these resembled glandular-fever cells. On day 6 about half the lymphocytes were atypical, and about a third of these had the character of glandular-fever cells. These atypical cells decreased in number and had disappeared from the blood by day 13. The haemoglobin level and platelet count were normal throughout the illness. Paul-Bunnell and toxoplasma dye tests were repeatedly negative. A sternal bone-marrow examination on day 7 showed no neutrophil myelocytes or leucocytes but an increase in promyelocytes and in eosinophil myelocytes and leucocytes. The increase in promyelocytes presumably represented a recovery phase rather than a maturation arrest, as neutrophil leucocytes reappeared and increased steadily in the peripheral blood shortly afterwards.

A woman aged 71 suffering from rheumatoid arthritis had been treated with phenylbutazone, 300 mg. daily for three weeks, when a general-

ized maculo-papular rash appeared, which was partly petechial on her legs. There was no lymphadenopathy and the spleen was not palpable. The results of blood counts are shown below.

Day of illness	W.B.C. /cu. mm.	Neutrophils /cu. mm.	Eosinophils /cu. mm.	Lymphocytes /cu. mm.
1	11,000	4,400 (40%)	1,210 (11%)	4,950 (45%)
3	17,000	5,780 (34%)	1,050 (5%)	10,030 (59%)
11	12,000	4,440 (37%)	3,480 (29%)	3,360 (28%)
24	9,000	6,390 (71%)	270 (3%)	1,890 (21%)

On days 1 and 3 nearly all the lymphocytes were atypical, and about half of these resembled glandular-fever cells. By day 11 the latter had disappeared and only an occasional lymphocyte was atypical. On day 24 the leucocyte picture was normal. The haemoglobin level and platelet count were constantly normal. Paul-Bunnell tests were repeatedly negative, and toxoplasma dye tests gave titres of 256 during and for three months after the illness.

It seems most unlikely that glandular-fever or toxoplasma infection was the cause of the illness in either case. Both infections are rare over the age of 50.^{2,3} Lymphadenopathy was not present, as it is invariably at some time in glandular fever³ and in cases of toxoplasmosis with glandular-fever cells in the blood.³ A toxoplasma dye titre of 256, as in Case 2, is found in 1% of adults, and the titre in the second case did not rise during or after the illness. On the other hand, the skin rashes and the marked eosinophilia, and the agranulocytosis in the first case, strongly suggest that both patients suffered a reaction to the drug phenylbutazone, and that the glandular-fever cells in the blood were part of this reaction. This was the conclusion of Dr. Lawrence as regards his case, which showed an even greater lymphocytosis of 17,820/cu. mm. with many glandular-fever cells present and an eosinophilia of 1,080/cu. mm.

I wish to thank Drs. J. Laurie, E. A. Murray, and I. D. S. Cowie for the clinical details and permission to publish these cases, and Miss J. Hutchinson for assistance.

Elastic Band Injuries

SIR,—Deliberate production of artifact ulcers by elastic bands around the lower third of the leg is described in the paper by Mr. I. D. Kitchin and others (22 April, p. 218) and in the letter of Dr. K. Dawson-Butterworth (20 May, p. 510). Accidental production of artifact ulcers by elastic bands around the fingers and around the arm is described by Dr. J. G. B. Thurston (6 May, p. 376) and Mr. J. P. Turney (13 May, p. 445), respectively.

A widow aged 77 presented in September 1967 with a deep circumferential ulcer of the lower third of the right leg and a chronic

varicose ulcer distal to this. She reported that a tight bandage had been applied to the varicose ulcer; this was postulated as the cause of the circumferential ulcer. The day after admission to hospital an elastic band

was removed from the depths of the ulcer. On further questioning she admitted having used an elastic band to hold a dressing on the varicose ulcer some weeks before admission, and had been perplexed at its disappearance.

The photograph was taken by Mr. A. D. Ring 24 hours after removal of the band.

Nalidixic Acid and Intracranial Hypertension

SIR,—There have been letters in the *B.M.J.* this year describing intracranial hypertension in children treated with nalidixic acid (29 April, p. 310; 5 August, p. 370; and 9 September, p. 679).

We therefore think it of interest to report the case of a middle-aged woman, who in the third week of acute glomerulonephritis, while yet still febrile and slightly oedematous, but with good urine output and blood urea of 24 mg./100 ml., was given nalidixic acid in a dose of 1 g. four times a day for a superimposed coliform infection of the urine. At the time she was normotensive and had no papilloedema. Within 24 hours of commencement of the nalidixic acid she developed, in the night, a toxic confusional state of schizoid type with paranoid ideas and depersonalization. A day later the nalidixic acid was stopped and there was thereafter considerable improvement, although another week passed before she was completely normal. An E.E.G. at this time was essentially normal, but during the record the patient had a hallucinatory episode during which there was demonstrated an increase of theta activity, abolished by opening the eyes. A repeat E.E.G. at a later date was entirely normal, though it is probably significant that the frequency of the alpha rhythm showed an increase of one cycle per second.

It would seem possible that the administration of nalidixic acid during the oedematous phase of acute nephritis precipitated this

psychosis. Such an occurrence bears a relation to the previous reports of intracranial hypertension, although in this case there was no direct evidence.—We are, etc.,

Newcastle upon Tyne.

Goodpasture's Syndrome and Dialysis

SIR,—The following case history supports the use of peritoneal dialysis in Goodpasture's syndrome, as mentioned by Dr. J. F. Munro and others (14 October, p. 95).

A 36-year-old woman was admitted in August 1966 with pyrexia. She had previously enjoyed good health and had borne five children with no apparent medical complication. She had noticed haemoptysis for the previous two weeks.

A postero-anterior chest x-ray showed bilateral diffuse mottling in the mid and lower zones. Haemoglobin was 6 g./100 ml. and the R.B.C.s showed the features of an iron deficiency anaemia. There was no other site of blood loss. The W.B.C. was 9,600/cu. mm.; the E.S.R. 125 mm. in one hour, and the blood urea 175 mg./100 ml.; serum proteins were 4.6 g./100 ml. with an albumin of 2.9 and a globulin of 1.7. Lupus erythematosus and rheumatoid arthritis screening tests were negative. Her sputum contained many macrophages laden with haemosiderin but no mycobacterium. The urine contained a moderate amount of protein. R.B.C.s and casts could be seen on microscopy.

Despite her sex, these features are in keeping with Goodpasture's syndrome. She was started on prednisone. Over the ensuing days haemoptysis continued and she complained of increasing dyspnoea. Her urine output fell. The blood urea slowly rose to 390 mg./100 ml., by which time she had become semi-conscious. Peritoneal dialysis was performed with dramatic subjective improvement and her urea fell to 222 mg./100 ml.

During the next two weeks she ate a low protein diet and her blood urea fell still further to 42 mg./100 ml. Haemoptysis ceased.

She then started to develop considerable oedema despite a reasonable fluid output and was prescribed frusemide. She commenced a normal diet. Average proteinuria was 1 g. per day, using Esbach's method at the time of discharge. Since that time she has remained in reasonable health up to August of this year, although her blood urea has slowly risen to 100 mg./100 ml. Episodes of haemoptysis have been infrequent.

The original peritoneal dialysis was life-saving during a critical part of her illness. She has recently been readmitted complaining of dyspnoea. Her haemoglobin is 10 g./100 ml. The blood urea has risen to 300 mg./100 ml.—I am, etc.,

General Hospital,
Burton-on-Trent.

DEREK BAINBRIDGE.

Cowpox and Paravaccinia

SIR,—I read your leading article "Cowpox and Paravaccinia" (November 11, p. 308) with great interest. How does the cow's udder become infected? What is the direct source of infection? Many country folk, and others, have quaint notions about this.

I quote from a rare copy of *Practical Observations on the Inoculation of Cowpox* by James Bryce, "one of the surgeons to the Institutions for the Gratuitous Inoculation of Cowpox, Edinburgh, 1801."

"Some have asserted that the cowpox is not generated in the constitution of the cow, but produced on her by inoculation with certain diseased fluids of the horse; while others are of opinion that this ailment is truly vaccine, being generated solely in the constitution of the cow."

"The horse, it is well known, is subject to an inflammation and swelling in the heels, which is called the grease, from which, at a certain period of the affection, there issues a very acrid thin matter; and this applied to the udder or teats of the cows . . . gives rise to a postular [sic] affection on those parts, which is the cowpox."

For all I know, Jenner himself may have proved this theory to be a scientific truth.—I am, etc.,

W. A. BRYCE.

Streetly,
Sutton Coldfield.

Percentages

SIR,—A minor annoyance in the reading of tabulated data is the habit of some authors of reporting the percentage of both positive and negative, leading the reader to check whether the figures do indeed add up to 100. This might be "planned redundancy," a common computer method of confirmation of a result or a method of emphasizing the figure.

But when a pair of figures put out by a computer do not add up to 100, as recently in the *B.M.J.* (2 September, p. 613), one wonders who or what has slipped.—I am, etc.,

Durban, South Africa.

** We apologize for the error in Table I in the article referred to.—ED., *B.M.J.*

Measurement of Blood Loss

SIR,—We were very interested in the paper by Dr. J. M. Holt and others (14 October, p. 86) regarding the measurement of blood loss using a whole body counter. Although this method is very convenient for the patient and the doctor, the considerable discrepancy between calculated blood loss and actual blood loss shown by the authors is alarming, and may limit the clinical usefulness of whole body counters in studying blood loss.

We have found that the method of detection of blood loss using radio-chromium-labelled red cells and faecal collections is a highly accurate way of detecting intestinal blood loss over a period of weeks. The method is sufficient to detect less than 0.5 ml. of blood and is equally applicable to menstrual blood loss.

The simplicity of this technique of faecal collection may well recommend itself for more routine clinical use, and in appropriate patients can be used as an outpatient procedure. The whole body counter is the ideal tool for iron absorption studies, but in view of the serious disadvantage in accurate detection of blood loss from our own experience

we would recommend faecal collection whenever possible using radio-chromium.—We are, etc.,

S. NASSER.

West Middlesex Hospital,
Isleworth, Middx.

Thiothixene in Schizophrenia

SIR,—Thiothixene (Navane, Pfizer) is a new addition to the group of tricyclic major tranquillizing and antipsychotic drugs. A number of controlled trials^{1,2} in other countries on acute and chronic schizophrenic patients have indicated a beneficial effect, principally on excitement and suspiciousness, and, in apathetic chronic schizophrenics, an activating effect. Dosages employed range from 5 to 60 mg. daily, with a mean of 30 mg. daily. Comparative studies have demonstrated a therapeutic range equivalent to thioridazine and trifluoperazine. The only consistent side-effects appear to be extrapyramidal, which respond to anti-Parkinson drugs.

We should like to report briefly an uncontrolled pilot study in 16 chronic schizophrenic patients consisting of nine females aged from 36 to 73 years, mean 55 years, and seven males aged from 25 to 48 years, mean 35 years. The duration of illness ranged from 3 to 40 years with a mean of 16 years. The psychosis took a paranoid form in six patients and a hebephrenic form in 10.

Thiothixene was given by mouth in an initial dose of 5 mg. daily, increasing gradually to a maximum of 40 mg. daily for a total period of 12 weeks. A number of target symptoms and the overall response were rated weekly and the occurrence of side-effects was noted. Weekly blood counts, liver-function tests, blood urea, and urinalysis were performed.

Overall improvement was observed in eight patients. In two patients, with duration of illness of 22 and 7 years, the response was quite dramatic, the former being able to return home and the latter being allowed into the hospital grounds without supervision for the first time. The target symptoms which showed the greatest response were excitement (six patients), suspicion (seven patients), depression (four patients), anxiety (six patients), and social inadequacy (eight patients). Extrapyramidal side-effects were observed in 11 cases, but in only two were they severe enough to warrant the use of anti-Parkinson drugs. Four patients were withdrawn from the trial before the end of the 12-week period; two because of poor clinical response, one because of uncontrolled extrapyramidal effects, and one because of a raised serum glutamic pyruvate transaminase (110 S.F. units/ml.) after three weeks.

Much of the response could be a placebo effect, but in view of the failure of these patients to respond to previous drug therapy, and the dramatic response in two patients, we think it is worth proceeding to a properly controlled trial.—We are, etc.,

K. DAVISON.
P. LEYBURN.
H. A. MCCLELLAND.

Therapeutic Effects of a Thunderstorm

SIR,—In Zurich, in 1732, a report was published on an unusually violent thunderstorm which had arisen in the night between 30 June and 1 July of the previous year. The report was the work of Johann Jakob Scheuchzer (1672-1733), the Swiss scientist known in the history of palaeontology as discoverer of the fossilized remains of a giant salamander. Early in the century he published accounts of his travels in the Alps, with detailed notes on the life and occupations of the people (including an illustrated description of the process of cheese-making), on flora and fauna, the movements of glaciers, and barometrical determination of altitude. Scheuchzer has been called the founder of the physical geography of the Alps. By profession a medical practitioner, he became physician in ordinary to his native city Zurich.

After a description of the storm and some theological observations characteristic of the period, Scheuchzer's report makes the following comment*:

"And how, if I were to assert that the very Thunder-storm must serve to sustain and promote our Health, inasmuch as in such mighty Perturbances not only the Mountains, Valleys, Forests, and Rocks, but also our Bodies do quake, and that the Circulation of the Blood and of all the radical Moistures is promoted and that all the Discharges are more readily effected. Moreover, the Terror itself which seizeth Men may make some Contribution, for that by its Agency the Influence of the sensitive Faculties upon the Upper Skin gains ascendancy and the littlest Vessels are compressed. To the which Cause I ascribe that various Persons of both Sexes, upon Inducement of this violent Storm, were some Days thereafter taken with a profuse Bleeding at Nose, as Instance a Widow of seventy Years, and plethorick, to whom I was summoned in the Night betwixt the third and fourth of July, and the same was freed by violent Bleeding at Nose from Giddiness and Head-akes, from the which she had suffer'd some Weeks before the Storm, and likewise eas'd of a Pursiness [or Asthma]."

Among conditions to which response may be expected Scheuchzer mentions pleurisy, running sores, rashes, "sickness of the limbs" (the term appears to have included "joint-gout," "the palsy," in general "sickness wherein there is resolution of the sinews and limbs"),† and all kinds of fever.

Beyond such details as are given in the quotation no attempt appears to be made to postulate the mechanism of the process by which the alleged cure is brought about. It may or may not be relevant to point out that Scheuchzer died some four years before the birth of Galvani and 12 years before the birth of Volta. Whether the question of electric discharge comes into the picture or not, it would perhaps seem that the Swiss physician had some inkling of the nature of shock-therapy.—I am, etc.,

WILLIAM F. MAINLAND.

The University,
Sheffield.

* There appears to be a Latin version of the report, which I have as yet been unable to consult. The present excerpt is my own translation from the German into English as nearly equivalent as possible to the vocabulary and style of Scheuchzer.

† See Christian Ludwig, *Deutsch-Englisches Lexicon*, 3rd ed., Leipzig, 1765.

Approval of Emergency Treatment Service

SIR,—The suggestion made by Dr. M. Mundy (4 November, p. 299) that the organizers of the B.M.A.-sponsored Emergency Treatment Service are unable to provide a viable service makes curious reading for those subscribers in the several cities where such a service has been running successfully for several years. That the service has so far failed to take hold in London would suggest that medico-political influences are involved, otherwise it is difficult to see why a scheme which has proved acceptable to executive councils in Bristol, Coventry, Glasgow, Leicester, Newcastle, Nottingham, and Sheffield should prove too difficult for the London Executive Council.

The criticisms that Dr. Mundy makes of the service are based on a misunderstanding of the type of service that is available, an integral part of which is that advice is given by the telephone operators (all State Registered Nurses) to a substantial proportion of the calls made to it. It is for this reason that a subscriber needs to be a member also of the Telephone Answering Service Ltd., as the staff need to have control of all incoming messages for which they are accepting responsibility. This does not mean that the subscriber loses control of his phone; he need hand over only during the time he is having cover from the E.T.S. The low cost (a guinea a month) of the Telephone Answering Service is surely sufficient answer to the allegations that this proviso is designed to make a profit. The attraction of this service is such that there are a substantial number of doctors who use it here in Bristol but who do not yet subscribe to the E.T.S.

The inefficiency of the G.P.O. transfer service is deplorable, but many of us are forced by circumstances to use it whether we use the E.T.S. or not, and criticism of this is irrelevant to the merits or otherwise of the E.T.S. But it is worth noting that even this service seems to have improved to some extent since the transfer number has been to the E.T.S. It is certainly absurd that in a so-called technological age it is not yet possible to make a transfer by simple switching; this problem must be solved by

the G.P.O. and the introduction of modern equipment.

The second complaint, that the E.T.S. is too expensive, also falls into perspective when it is realized that advice is given to a considerable proportion of calls, and if these are included in the statistics the cost per call falls to a much lower figure. I would suggest that in any case this is a highly artificial way of looking at it. What is important to the individual subscriber is not the actual number of calls done for him but the potential hours of freedom available with E.T.S. cover, even though only some of these hours may be actually used. The subscription can then be viewed in part as a type of insurance premium (with full tax relief), the total number of calls being relatively unimportant. The figure of 25 calls a month is an upper figure and irrelevant, and presumably included only to avoid the possibility of abuse of the service. It is the instant availability of the service that has proved to be its chief attraction to some of us; this advantage might seem even more cogent to potential subscribers with the advent of breathalyser tests. If the service was really so expensive, as its detractors constantly state, one would expect subscribers who found it so to resign from it; but this does not happen.

At a meeting in Bristol the financing of the service was explained very fully by the manager there, and it was made quite apparent that if you have a service which depends on the use of telephone operators who are State Registered Nurses, and locums experienced in general practice, the subscription cannot be lowered without sacrificing existing standards. Whatever may be the theoretical objections to these criteria, in practice the service is not only viable but successful. If a valid opinion is really wanted about the E.T.S. I would suggest that a survey carried out among subscribers in the cities where it operates would provide this more accurately than casual letters to the *B.M.J.*—I am, etc.,

A. DOWLING.

St. George Health Centre,
Bristol 5.

utilize its publicity outlets, and keep pressure on Divisions to ensure that the scheme was sold for both active and latent use. Surely we are not once more to wait until the apathetic mass of doctors revolt before the B.M.A. struggles to regain some form of leadership. The concept of I.M.S. may not have been to the liking of all, but at least, organized thoroughly at Division levels, we should now be in a position to face any eventuality in the political jungle without fear.—I am, etc.,

Peterculter,
Aberdeenshire.

Casualty Staffing

SIR,—As a general practitioner and a casualty clinical assistant, I was interested to read Mr. Guy Rigby-Jones's letter on casualty staffing (11 November, p. 360).

Since the advent of Birmingham Emergency Locums Ltd.—a general-practitioner deputizing service—an interesting pattern has been emerging. Junior and senior hospital staff in their off-duty periods are largely staffing Birmingham Emergency Locums Ltd. (I understand that this is for primarily financial reasons.) General practitioners, on the other hand, are occupying what spare time they can arrange in order to staff their local casualty units.

This interchange as well as having a financial benefit also has the advantage that the general practitioner keeps in touch with the hospitals, and the hospital staffs gain first-hand knowledge of the problems of general practice. One obvious point is that this existing exchange of roles is reaching equilibrium. House-officers like to enjoy their hard-earned leisure and general practitioners like some time for relaxation. Any strain on either side results in the potential collapse of the whole. Until there are more house-officers and general practitioners available for this interchange then any stresses in the system may prejudice the whole.—I am, etc.,

Yardley,
Birmingham.

BERNARD A. JUBY.

Independent Medical Services

SIR,—With reference to your report on the proceedings of Council (*Supplement*, 4 November, p. 29), I feel we at the periphery should have something to say in this rather pathetic business of Independent Medical Services (I.M.S.).

No one who has read the Council proceedings in the past can have been other than dismayed at the apparent isolation that Dr. Ivor Jones and his Committee have found themselves in over I.M.S. Council members appear to conveniently forget their past remarks, but the records will show that many seem to prefer their own views to fully implementing the will of the profession as set down in Annual Representative Meeting resolutions.

Council must also fully realize that Dr. Ivor Jones should never have been left to promote the scheme direct to the profession. The fact that reference is made to "Ivor

Jones's Private Army" reveals a thought association with an individual, and I doubt whether Dr. Jones's image as the man who stood out against the Memorandum of Evidence to the Review Body (Doc. S.C.7)¹ endears him sufficiently to the inactivists among us to further the scheme.

Also, the Private Practice Committee is, in these days of the N.H.S., looked on as a relatively minor committee of the Association and treated as such by the majority of doctors, so why should a scheme, apparently introduced by it, carry much weight. After all, the General Practitioners Association circularized interested general practitioners with their scheme prior to I.M.S., and, on casual inspection, no great difference was apparent, in either content or sales drive, between the two.

No, it was the duty of the B.M.A. to openly proclaim its parenthood of the scheme,

Christmas Cards for Medical Charities

SIR,—As in previous years, I should like to take this opportunity of reminding all readers that Christmas cards are available for purchase from B.M.A. House, all profits from which go to medical charities. The number of applications for assistance which are received by the various funds is continuing to increase, and any support given to the funds by members of the profession to help their less fortunate colleagues or their dependants will be greatly appreciated.

Details of the design and cost of the cards may be obtained on application to the Bursar, British Medical Association, B.M.A. House, Tavistock Square, London W.C.1.—I am etc.,

R. COVE-SMITH,
Chairman, Charities Committee,
British Medical Association.

London W.C.1.

Obituary Notices

D. J. McI. IRVINE, M.B., CH.B., F.R.C.O.G.

Dr. D. J. McI. Irvine, consultant obstetrician and gynaecologist to the Edinburgh Royal Infirmary and Simpson Memorial Maternity Pavilion, died very suddenly on 12 November at his home at Newbridge, Midlothian. He was 50.

Donald James McIntosh Irvine was born at Kingussie on 13 February 1917. It was there that his deep and continuing love of the hills, of the countryside, and of the many outdoor pursuits at which he excelled began, and so coloured his life and outlook. Indeed he was out riding with his daughter when he became ill. As a student he played shinty for Edinburgh University and finally captained the team. He graduated M.B., Ch.B. from Edinburgh in 1940, and after a short time in resident hospital appointments he joined the R.A.M.C. He served with the 52nd Lowland Division, with the 150th Tank Regiment, and also in military hospitals in South-east Asia and in Belgium. After demobilization he specialized in obstetrics and gynaecology, and for a good many years held a consultant appointment at Bangour General Hospital as well as at the Edinburgh Royal Infirmary. He took a major part in developing the department at Bangour, and in establishing the obstetrical service in West Lothian. A first-class clinician and a popular and effective teacher, he yet took his full share

not only in the corporate life of the Edinburgh medical school but in the wider medical circles. He became a member of the Royal College of Obstetricians and Gynaecologists in 1950 and a Fellow in 1962. He was a Fellow and senior secretary of the Edinburgh Obstetrical Society and a member of the Gynaecological Visiting Club of Great Britain. His contributions to the literature of the subjects usually took the form of clinical surveys.

Added to and always enhancing Donald Irvine's high professional excellence was his most kindly and generous understanding, his vitality, and his gay optimism. He could never say no to any call for help or advice, be the problem great or small, professional or lay; nor did he spare himself in his giving, for he always went the second mile. He was held in the highest esteem by all who knew him, and many are those who will remember him with deep gratitude, and who, with his colleagues, now mourn his untimely passing.

His was a happy home on the outskirts of Edinburgh. This, in such little spare time as he was allowed, he could enjoy with his family and pass on to them his enduring love of nature. We offer our respectful sympathy to his widow, his daughter, and his two sons. —J. S.

K. S. KIRBY, D.SC., PH.D.

Professor K. S. Kirby, of the Institute of Cancer Research, died at his home in Amersham, Buckinghamshire, on 10 November after a long illness which he never allowed to cloud his natural cheerfulness. He was 49.

Kenneth Stanley Kirby was born in Yorkshire on 16 January 1918, and, although he spent little of his adult life in the county,

he retained a strong affection for the attitude to life of the traditional Yorkshireman. He graduated B.Sc. with first-class honours at the University of Manchester in 1940. He then worked in the Wellcome Laboratories for Tropical Medicine on the chemotherapy

of amoebiasis and on the structure of alkaloids. After the war Kirby returned to academic life and obtained his Ph.D. at Leeds in 1949. He continued to work on the structure of tannins—the subject of his thesis—when he joined the Forestal Research Laboratory in Harpenden. During this time he gained considerable experience of analy-

tical and preparative procedures necessary for the study of complex organic substances.

In 1953 Kirby joined the staff of the Chester Beatty Research Institute (of the Institute of Cancer Research, Royal Cancer Hospital). He worked firstly as a Fellow of the British Empire Cancer Campaign and subsequently on the permanent scientific staff at the Institute's research station at Pollards Wood, Chalfont St. Giles, Bucks. His previous experience and natural aptitude fitted him extraordinarily well for the contribution he was to make to the study of cellular macromolecules. He rapidly obtained international fame for his development of the phenol method for the isolation of nucleic acids. It was his thorough appreciation of the chemical problems involved in protein-nucleic acid interaction coupled with a careful experimental approach which enabled him to develop these procedures for general application to a wide variety of cell and tissue material. At the same time he was utilizing these techniques in studies of carcinogenesis at the molecular level. In this he was joined by a constant stream of visiting workers from many countries, all of whom acquired not only valuable experience but also lasting friendship.

Kirby was awarded a D.Sc. by the University of Manchester in 1964, and the title of professor of cell chemistry was conferred on him in February 1967. These were unsought honours richly deserved. He will be remem-

bered affectionately by his colleagues both for his deep chemical knowledge and for his free-ranging sense of humour and thorough enjoyment of living.

Professor Kirby leaves a widow and four children, to whom we and his many other friends extend the deepest sympathy.—A. R. C.

L. G. EDDEY, M.B., CH.B., D.P.H. D.T.M.&H.

Dr. L. G. Eddey, chief medical officer to the Ministry of Health at Blantyre, Malawi, and former W.H.O. area representative in India, died in hospital in Salisbury, Rhodesia, on 22 October. He was 64.

Leslie George Eddey was born in Devonport on 14 October 1903. He joined the Colonial Service, and in 1928 went out to the Gold Coast (now Ghana), where he worked as a superintendent health inspector. After a few years, deciding to take up medicine, he returned to Britain and entered Aberdeen University, graduating M.B., Ch.B. in 1938 and taking the D.T.M.&H. a year later. Shortly afterwards he became a medical officer on the Gold Coast, where he remained until 1946, when he left to take up the appointment of deputy director of medical services in British Guiana (now Guyana). He took the D.P.H. in London in 1949, then returned to the Gold Coast to take up the appointment of chief medical officer to the Ministry of Health there before accepting a two-year appointment with the World Health Organization in Nepal, where he helped to establish a school for the training of health assistants in Katmandu. In 1957 he joined the staff of the W.H.O. regional office for south-east Asia in New Delhi as public health administrator, becoming area representative for India from 1960 to 1963. For the next three years he was W.H.O. medical consultant for the Asian Institute for Economic Development and Planning in Bangkok, Thailand, later accepting the appointment of chief medical officer to the Ministry of Health in Malawi, Central Africa, where he was working up to the time of his death.

A colleague writes: Dr. Eddey, besides being hard-working and efficient, and of a disposition that made him enjoy whatever he was doing, was so full of enthusiasm and *joie de vivre* that he immediately made friends wherever he went. He liked people and enjoyed being with them. He loved to entertain and did it so graciously that everyone enjoyed being invited to his flat. His many friends will feel a real sense of loss.

B. B. W. writes: Leslie Eddey had the remarkable record of serving in the Gold Coast as a health superintendent, later as a medical officer of health, and finally, after a period in British Guiana, as chief medical officer. He was a bachelor, with a personality that seemed to be gentle to the point of diffidence. Gentle he certainly was, but not diffident. In the Gold Coast, and in British

Guiana, where also he was chief medical officer during the period of rapid political advance, he was faced with the position of increasing responsibility but greatly diminished power. His undoubted success was due to his ability to assess the personalities of those around him, and to get them on his side, acting as he thought best. This persuasiveness was not a deliberately developed technique, which would have earned him enemies. It came from confidence in his own knowledge combined with an earnest desire not to make others (with less knowledge or mistaken views) feel foolish. He persuaded a sanitary labourer, or a rural medical officer, in precisely the same way as a Minister of Health, and with a patent and sincere friendliness that was returned spontaneously by everyone he knew. On the rare occasions when he himself was won over by persuasion he accepted the new viewpoint without a trace of wounded vanity.

He was an excellent host and a man whose friendship lasted over the years—he sent off several hundred Christmas cards every year. When he finally left the World Health Organization his appointment as chief medical officer of Malawi seemed to be an ideal one for the country and for himself. It is indeed sad that he should have died so soon, but he would have died in harness somewhere; he was too devoted to the ideals of public health to retire.

J. T. BARR, M.B., B.S., F.F.A.R.C.S.

Dr. J. T. Barr, formerly anaesthetist to the neurosurgical unit at the Brook Hospital, Woolwich, died at his home on 31 July. He was 63.

John Templeton Barr was born on 17 November 1903, and was educated at Repton School and King's College Hospital Medical School, London, qualifying with the Conjoint diploma in 1926 and graduating M.B., B.S. a year later. He held resident posts at the Miller General Hospital, Greenwich, and was later appointed medical officer to the District Hospital at Erith, Kent. He took the diploma in anaesthetics in 1941. During the second world war he served as major in the R.A.M.C. and as anaesthetist under the Emergency Medical Service. After the war he was appointed anaesthetist to the neurosurgical unit at Joyce Green Hospital, Dartford, becoming anaesthetist to the South-east Metropolitan Regional Surgical Centre and Woolwich group of hospitals in 1946. In 1954 he was elected F.F.A.R.C.S. Ill-health forced him to retire in 1966.

G.C.K. writes: John Barr joined the staff of the South-east Metropolitan Regional Neurosurgical Unit as an anaesthetist in the early days of the development of the unit in 1946, and we were most fortunate that he did so. He worked with us for more than 20 years until the time of his retirement through failing health in 1966. He was a most excellent colleague, a man of great sympathy and charm, and a highly skilled anaesthetist who brought to the special problems of anaesthesia in neurosurgery a high standard of skill which undoubtedly contributed materially to the results obtained in this centre over a period of many years. He was unsparing of self in the care of his

patients, and continued to take part in long operations when his own health was failing through the effects of myeloid leukaemia. Such was his devotion to his work that he carried on when other men would have given up. He was a man of great personal courage whose charm endeared him to all around, and in his passing we have lost a great friend.

H. W. PALMER, M.B., B.S.

Dr. H. W. Palmer, a general practitioner in Worthing for over 21 years, died in Worthing on 29 September, aged 62.

Horace Winston Palmer was born in London on 21 June 1905, and came late into medicine after a successful commercial career. He graduated B.Sc. with first-class honours at Queen Mary's College, London, in 1926, and was instrumental in starting the analytic laboratory at Messrs. Heinz Ltd., which he conducted until he was called away to become managing director of the family business in Brighton. He held a civil pilot's licence at the outbreak of the second world war, and, on being rejected for flying duties with the R.A.F. because of age, decided to take up medicine. He entered Guy's Hospital in 1940 and graduated M.B., B.S. in 1944, taking the Conjoint diploma in the same year. After resident appointments in Pembury Hospital, Hove General Hospital, and St. Richard's Hospital, Chichester, he entered general practice in Worthing in 1946, and was hard at work in it on the day of his death.

Dr. Winston Palmer was a member of the West Sussex Medical Committee, and served on the council of the Brighton and Sussex Medico-Chirurgical Society. He was a founder member of the Royal College of General Practitioners, and was the local Treasury medical officer. A keen Mason for over 35 years, Winston Palmer's interests were many and varied, from rock-climbing and sailing to music and photography. He was a patron of drama and the arts, and was an indefatigable opera-goer. His great love, however, was always medicine, with a special interest in psychiatry. He will long be remembered with gratitude and affection for his unfailing kindness, sympathy, and patience.

In the last three years of his life Winston Palmer was often far from well, and was several times in hospital. His courage to overcome his illness, his unselfishness, and his devotion to his vocation won the admiration, respect, and affection of his many friends and colleagues. We extend to Dorothy, his widow, and their three children our sympathy in their grievous loss.—T. M.-G.

F. W. EARLE, M.R.C.S., L.R.C.P.

Dr. F. W. Earle, for many years in general practice in Garston, Liverpool, died on 11 October after a very short illness. He was 63.

Francis William Earle, son of William Kynsey Earle, was born on 18 September 1904. He was educated at Stonyhurst College and the University of Liverpool, from

which he qualified with the Conjoint diploma in 1928. He held house posts at the Royal Southern Hospital, Liverpool. After a brief period of postgraduate study in surgery, he spent much of 1931 with the New Zealand Shipping Line as ship's surgeon. It was while serving on T.S.S. *Devon* near Panama that he met with great resource the kind of desperate situation which occasionally falls to the lot of the lone doctor at sea. Help was sought from another ship for a Spanish seaman who had been stabbed in an affray. Francis Earle was rowed across to the foreign vessel, and with simple instruments and primitive facilities successfully repaired not only the abdominal wound but injured viscera as well. The letters of gratitude from the Spaniard are still treasured by his family. On returning to Liverpool Earle entered a partnership in general practice in Garston—an industrial and residential suburb of Liverpool—with its own busy accident hospital, the Sir Alfred Jones Memorial Hospital. Here he found scope for his surgical abilities, and he served the hospital with distinction until the reorganization brought about by the National Health Service. He met the formidable demands of his practice with characteristic calm, energy, and devotion, and on the death of his partner in 1961 he continued working single-handed.

After his work his absorbing interest from earliest days was in sailing. His yacht, *Spray*, was moored off Garston or off Anglesey, whence he sailed up and down the west coasts of England, Wales, and Scotland, and in Irish waters. He was a member of the Royal Mersey, Royal Dee, and Royal Anglesey yacht clubs, and often participated in the annual midnight race from the Mersey to the Isle of Man. It is characteristic of him that, ignoring menacing premonitory symptoms, he attended a navigation class on the evening before he died.

His passing is widely mourned by patients and colleagues alike. Close friends knew something of his loyal, self-sacrificing, and sustained endeavours on behalf of less fortunate colleagues. He was married to Maureen, daughter of the late Dr. W. F. McCann, of Liverpool, who survives him with a son and daughter.—R. W. B.

G. M. CLARK, M.B., B.S., D.OBST. R.C.O.G.

Dr. G. M. Clark, mission doctor in Tanzania, died suddenly on 23 October at Mnero Hospital, Tanzania. He was 40.

George Miles Clark, son of the late Dr. George Clark, of the Ministry of Health, was born on 2 February 1927, and received his medical education at University College Hospital, London, graduating M.B., B.S. in 1957, and taking the D.Obst.R.C.O.G. two years later. He held resident posts at University College Hospital, Perivale Maternity Hospital, Greenford, and Mundesley Hospital, Norfolk, before going out to Mnero Hospital, Nachingwea, Tanzania, a mission hospital in one of the more remote and poor parts of the country. His medical and surgical skill was rapidly appreciated by many grateful patients, and he was loved by a large number of the poor.

They appreciated in him a man of essential humanity, try as he often would to conceal this behind a self-effacing gruffness or a blunt Yorkshire turn of phrase.

Miles Clark was a good companion with no frills—"a foul-weather friend"—and his pithy descriptions of events which had befallen him were often masterpieces of narrative understatement. During his comparatively short life he had to fight adversity in many forms, and this he always did fearlessly, with the help of his Christian ideals coupled with a courageous sense of humour. The world, and particularly the underprivileged part where he spent his most fruitful days, can ill afford to lose so prematurely one so valuable. He truly spent himself before his time.

To his widow and his mother is extended deepest sympathy.—R. E. D.

**W. STEADMAN, M.C., M.R.C.S.
L.R.C.P.**

Dr. W. Steadman, formerly in general practice in Ledbury, Herefordshire, died in hospital on 22 October at the age of 75.

William Steadman was born on 14 December 1891, and received his medical education at University College Hospital, London, qualifying with the Conjoint diploma in 1916. He joined the R.A.M.C. and served in France, where he was awarded the Military Cross. After demobilization with the rank of captain he returned to University College Hospital and held resident posts there before entering general practice at Snettisham, Norfolk. In 1934 he joined the late Dr. Leslie Trotter in practice in Ledbury, and remained there until his retirement in 1959 to the house in Wales in which he was born.

Bill Steadman was a big kindly man, who won many friends among both his patients and his colleagues, and his hospitality and generosity were widely extended. He was a keen and a good shot, and a knowledgeable and successful collector of antique furniture. The latter years of his retirement were marred by ill-health, but were spent in the peaceful and beautiful countryside and home that he loved.

Our sympathy is offered to his wife, and to their daughter and son.—D. B.

**T. R. TROUNCE, M.R.C.S., L.R.C.P.
L.D.S.**

Dr. T. R. Trounce, a former general practitioner in Cheshunt, Herts, died on 2 October, aged 77.

Thomas Reginald Trounce was born at Waltham Abbey on 1 September 1890, and attended school at Holt House, Cheshunt, until the age of 15, when he was apprenticed to a dentist. In 1911 he qualified as a dentist, and, deciding to take up medicine, he entered Guy's Hospital, where he qualified with the Conjoint diploma in 1914. Serving as a houseman at the Royal Surrey County Hospital, Guildford, looking after casualties from France during the first world war, he met a nurse who was subsequently to become his wife—and partner in every sense of the

word. Joining the R.A.M.C., he served in Gallipoli at Suvla Bay, contracted paratyphoid in Alexandria, and was later posted to France. He was medical officer on a barge on the Somme, and later worked on an ambulance train based on Abbeville. After demobilization he returned to Guy's as house-physician and resident obstetrician. In 1919 he went into general practice as partner to Dr. Greene, of Cheshunt. The practice grew rapidly with the increase in population of the area, and there were six partners when Dr. Trounce retired in 1958.

He worked for much of his life under considerable physical handicaps, for in 1930 he developed syringomyelia affecting one hand, and received treatment at intervals throughout his life. He overcame this to such an extent that he was able to continue in practice until he retired at the age of 68. In this effort he was greatly aided by the untiring help and care given to him by his wife, who died after his retirement. As a doctor he was skilled in spite of his disability. He displayed wisdom and judgement in his decisions; he was infinitely patient, no demand, however trivial or unnecessary, upset him; he would answer a call at any time without demur. A devout Christian, with his kindness, gentle humour, and humility he had the gift of evoking affection in all who met him.—J. A. C.

S. B. REA, M.B., B.Ch., B.A.O.

Dr. S. B. Rea, anaesthetist at Carshalton War Memorial Hospital, died suddenly at Findon, in Sussex, on 24 May. He was 65.

Samuel Brown Rea was born in Belfast on 18 November 1901. He was educated at the Belfast Royal Academical Institution, and graduated M.B., B.Ch., B.A.O. at Queen's University, Belfast, in 1926. After an early appointment at the Royal Victoria Hospital, Belfast, he came to England and worked as an assistant in South London. In 1927 he went into practice in Sutton and Carshalton.

In 1941, at the relatively late age of 40, he volunteered for service and was commissioned in the R.A.M.C. From 1942 he served in the Indian and South-east Asian Commands, attaining the rank of major as a specialist anaesthetist. After demobilization he returned to his practice with the added interest of posts in anaesthesia at the Carshalton War Memorial Hospital and later at the Sutton General Hospital. Pressure of work coupled with ill-health forced him to relinquish his post of anaesthetist at Sutton General Hospital and later his general practice, but he continued his association with the Carshalton War Memorial Hospital until his final retirement.

Dr. Rea was respected by his colleagues both as an anaesthetist and as a general practitioner of the old school. He was a man of great personal integrity, and his life was moulded by a loyalty to his patients and his colleagues, and by a deep and sincere patriotism. He had an abiding interest in human relationships, and under a volatile and sometimes brusque exterior one was conscious of a deeply sensitive and even sentimental character. His relaxations were found in boating, music, and reading, and in the

company of his beloved family and of his friends. Our very sincere sympathy goes to his wife and to his daughter, who sustained this loss only a few short months after his retirement.—C. F. C.

M. B. GEE, M.B., CH.B., D.C.H.

Dr. M. B. Gee, a general practitioner at Barking, Essex, died suddenly at his home on 24 October, at the age of 38.

Michael Barnett Gee was born in London on 20 August 1929, and received his early education at Bournemouth School. He entered Bristol University, graduating M.B., Ch.B. in 1953, and held early house appointments at Southend and at the Royal Children's Hospital, Bristol, before joining the Royal Air Force and serving in Libya. After demobilization he undertook further hospital work in otolaryngology and paediatrics before taking the D.C.H. in 1958. He entered a busy partnership practice at Barking, and was also appointed school medical officer there.

In his teens Michael Gee was deeply interested in modern music, particularly that of Stravinsky and Bartok, and he became an accomplished pianist and clarinet player. He read a great deal, and introduced many of his friends to the works of the great writers and composers. Recently he had taken an interest in archaeology, becoming an associate of the Institute of Archaeology and taking part in archaeological field work. He combined many talents, but above all he was a first-rate and devoted family doctor.

He will be sadly missed by his colleagues and friends and by his patients. Our greatest sympathy is felt for his wife and three small children.—H. P.

**Sir ARCHIBALD GRAY, K.C.V.O.
C.B.E., T.D., LL.D., M.D., F.R.C.P., F.R.C.S.**

B. L. writes: His friends and admirers all over the world will feel a sharp sense of personal loss at the passing of Sir Archibald Gray (obituary, 21 October, p. 178). I knew Sir Archibald from 1933, and feel sure that my meeting with him was the vital factor in my becoming established as a dermatologist. He was so shy and modest that his almost startling integrity may have been misunderstood by some, but it was truly a godsend to anybody who, through race, creed, or sex, may have had difficulty in becoming established without his help. His courage was clearly shown towards the end of his life, when he refused to admit defeat in spite of being so greatly handicapped. Whoever had the benefit of his wonderful personality and teaching ability must give thanks for having known and loved this remarkable man.

A memorial service for Dr. R. Hale-White will be held at St. Peter's Church, Vere Street, London W.1, at 12.30 p.m. on Monday, 11 December.

News and Notes

EPIDEMIOLOGY

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of whooping-cough and scarlet fever in England and Wales. Figures for 1967 are compared with the highest and lowest figures for each week in the previous years shown.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending 4 November (No. 44) and corresponding week 1966.

Figures of cases are for the countries shown and for Greater London. Figures of deaths and births are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland whence returns are approximate

includes primary and influenza pneumonia

includes puerperal pyrexia

first came DF 118...
for severe, intractable pain

then came Onadox-118...
for rheumatic pain

and now 

Paramol-118

Trade Mark

Each tablet contains:—

Paracetamol BP	500 mg
Dihydrocodeine bitartrate (DF 118)	10 mg

for all conditions where relief of moderate to severe pain is required—and in the management of chronic rheumatic conditions when aspirin is contraindicated.

Paracetamol has analgesic and antipyretic actions similar to those of aspirin, but it is relatively free from undesirable side-effects.

Dihydrocodeine bitartrate (DF 118) has been widely used for a number of years as a powerful analgesic; it has no sedative or hypnotic properties.

Detailed information will be supplied on request
DUNCAN, FLOCKHART and EVANS Ltd LONDON E2

Beyond The Pill... Mixogen...

as dramatically successful in preventing menopausal distress
as are the oral contraceptives in family planning.

The woman who uses an oral contraceptive during her later potential child-bearing years need not fear menopausal problems. But for those not 'on the Pill' when reaching the menopause, a hormone problem remains. *At the menopause three out of four women require hormone replacement.* Mixogen fulfils their need. The preparation, a finely balanced combination of oestrogen and androgen, acts synergistically to ensure complete relief of all menopausal symptoms. And it does so without recourse to sedatives which—apart from other considerations—fail to deal with the underlying cause of the symptoms.

Formula and Packs

Ethinylloestradiol B.P. 0.0044 mg and Methyltestosterone B.P. 3.6 mg per tablet.
Bottles of 25, 100 and 250. Literature and samples on request.

PARLIAMENT

Questions in the Commons

[FROM OUR PARLIAMENTARY CORRESPONDENT]

Consultant Service Delays

Mr. H. BOARDMAN (Leigh, Lab.) asked the Minister of Health on 20 November if he was aware of the delays in the hospitals' consultant service and of the priority being given to fee-paying patients; and what action he proposed to ensure that priority is accorded strictly on medical grounds.

Mr. K. ROBINSON: "I am aware that there are some delays in obtaining appointments for non-urgent conditions at consultative outpatient departments, and that it may sometimes be possible to obtain a private consultation more quickly. I have no evidence, however, that patients who require hospital treatment without payment after a private consultation are allowed any priority greater than that appropriate to their medical condition, but I shall be glad to look into any particular case."

Dr. DAVID KERR (Wandsworth, Central, Lab.) asked how many part-time and full-time consultants, respectively, were appointed in each of the three latest years for which figures are available.

Mr. ROBINSON: Excluding senior hospital medical officers with allowances specially

regraded as consultants, the numbers appointed were as follows:

Year ending 30 September	Full-time	Part-time
1964	131	193
1965	194	236
1966	190	222

Hospital Doctors

Dr. JOHN DUNWOODY (Falmouth and Camborne, Lab.) asked how many doctors were employed in each grade as junior hospital doctors; and how many of each grade were on the temporary register.

Mr. ROBINSON: The numbers at 30 September 1966 were:

Grade	All staff	Staff on Temporary Register
Registrar ...	4,281	343
Junior Hospital Medical Officer	194	7
Senior House Officer	3,503	541
House Officer ...	2,374	150

Ampicillin

Mr. T. FORTESCUE (Liverpool, Garston, Con.) asked the Minister of Health whether he had yet received an assurance from a Dub-

lin firm that it had withdrawn from circulation the batch of drug labelled ampicillin but known to contain not ampicillin but penicillin V.

Mr. J. SNOW, Parliamentary Secretary: "Yes. The firm disputes the reported analysis but has informed me that each purchaser has been asked to return remaining supplies of the batch concerned and that these are being sent to independent analysts."

Questions in the Lords

Cervical Cancer Tests

LORD KENNET, speaking for the Ministry of Health in the House of Lords on 15 November, stated that the returns from hospital authorities in England and Wales showed that in June this year women were being tested for precancer of the cervix at a rate of nearly 119,000 a month, or over 1,400,000 a year. This showed an expansion of 17% over the figures for June 1966. The numbers of technicians trained in cytology, and in post in June this year, was 605, an increase of 32% in 12 months, though not all of these were employed full-time on routine cervical cytology. These numbers, he said, should be adequate to provide the service needed, but the distribution of technicians varied and there were some areas where more were needed.

MEDICO-LEGAL

No Damages for Negligence

[FROM OUR LEGAL CORRESPONDENT]

A hospital was found by the High Court to have been negligent in its treatment of a nightwatchman who had consumed arsenic, but in the absence of proof that the negligence had caused his death the nightwatchman's estate failed to recover damages from the hospital.

At about 5 a.m. on 1 January 1966 Mr. William Patrick Barnett, of West Norwood, London, drank tea with two fellow employees at the Chelsea College of Science and Technology, where he was employed as a night-watchman. The tea contained arsenic, which killed Mr. Barnett. At the inquest the verdict was murder by a person or persons unknown, no explanation of the presence of the arsenic being found.

Mr. Barnett's widow, suing as administratrix of her husband's estate, sought to establish a claim for damages against the Chelsea and Kensington Hospital Management Committee by reference to events between the tea-drinking and the subsequent death.

Within 20 minutes of drinking the tea all three men vomited and continued to vomit for three hours. At 8 a.m. Mr. Barnett drove his workmates and himself to St. Stephen's Hospital, Chelsea. There was no receptionist on duty, and they entered the

casualty department, where they saw a nurse whom they informed of their symptoms. During the interview Mr. Barnett lay across some chairs. The nurse telephoned the casualty doctor on duty, who said that he himself had been vomiting, and instructed that the men should be sent away and told to go to their own doctors.

Mr. Barnett drove the other two men back to the college, where he was seen in distress at various times in the morning by fellow employees. Finally, at 1 p.m. a fellow employee sent for the college doctor, and Mr. Barnett was sent by ambulance to St. Stephen's Hospital, but was found to be dead on arrival.

The duty owed by the hospital to these men differed from the duty owed to persons already admitted to hospital wards. No case bearing directly on the duty owed to persons presenting themselves at casualty departments before being treated or received into the wards was cited to the court. A hospital does not owe a common law duty to treat everyone or indeed anyone who presents himself to the casualty department. But this was not a case of a casualty department which had closed its doors. The men entered the department without hindrance, were interviewed by the nurse, who spoke to a doctor,

who replied with a message purporting to give advice. In these circumstances a relationship arose between the parties imposing on the hospital a duty of care toward the men.

The doctor fell short of his duty and was negligent. It was the view of the judge, on the evidence, that though a casualty doctor was not under a duty to see every caller at the department he should undoubtedly see a man who complained of vomiting for three hours. But the evidence had shown that the difficulties inherent in diagnosing arsenic poisoning would make diagnosis too slow to have done Mr. Barnett any good. If Mr. Barnett had been admitted tests might have eliminated an initial diagnosis of food poisoning in favour of a suspicion of metallic poisoning. Further tests would then have been necessary to identify the poison.

When death resulted from arsenical poisoning it was brought about by two conditions—dehydration and disturbance of the enzyme processes. In Mr. Barnett's case the principal trouble was enzyme disturbance. Only administration of B.A.L. (dimercaprol) was likely to succeed, and B.A.L. would not be used unless arsenic poisoning was specifically diagnosed. There was no real chance of it having been administered before Mr. Barnett died.

The plaintiff's action failed. (*The Times*, 9 November).

MEDICAL NEWS

O.M. for P.R.S.

Professor P. M. S. BLACKETT, President of the Royal Society, professor emeritus and senior research fellow of Imperial College, London, has been appointed to the Order of Merit.

Award of Royal Medal

Professor J. Z. YOUNG, F.R.S., has been awarded a Royal medal "for his outstanding researches correlating neural structure with function." Professor Young was demonstrator in zoology and comparative anatomy at Oxford University from 1933 to 1945. Since 1945, when he became a Fellow of the Royal Society, he has been professor of anatomy at University College, London.

The Royal medals are awarded annually by the Sovereign on the recommendation of the Council of the Royal Society.

Chair of Dermatology

Dr. PATRICK JAMES HARE has been appointed to the chair of dermatology at Edinburgh University. Dr. Hare, who is 47, received his medical education at University College, London, where he was

Andrew's Scholar, and at University College Hospital Medical School. He also studied at Johns Hopkins School of Medicine, Baltimore, as a Rockefeller Student. Graduating in 1944, he was in the Royal Army Medical Corps from 1945

to 1948 and served in Burma and Singapore. He took up his first appointment at University College Hospital as registrar in the department of dermatology in 1948. In 1951 he spent a year in postgraduate study in Paris and Zurich as a Travelling Fellow of London University. He was appointed a consultant in the department of dermatology at his parent hospital in 1952 and took charge of the department in 1958 when he also joined the staff of the Whittington Hospital. Last year he was exchange professor in the department of medicine at McGill University, Montreal. Dr. Hare is the author of *Basic Dermatology*, published in 1966. His London M.D. was awarded for a thesis on necrobiosis lipoidica. He has been editor of the *British Journal of Dermatology* since 1958. His interests include comparative pathology, embryology, and the history of medicine.

Gift to Hospital for Research

Through the Variety Club of Great Britain Mr. MICHAEL SOBELL, industrialist, is to give £100,000 to the Hospital for Sick Children, London, to promote research into the causes of congenital malformations. The club states that the gift will provide a floor of research laboratories in a new building at Great Ormond Street that will also accommodate a heart surgery unit for children. It is expected that the building will be opened in 1969.

Proposals for Hospital Transfer

At a meeting in London on 13 November the North-west Metropolitan Regional Hospital Board approved proposals that will, with the approval of the Ministry of Health, result in the transfer of Paddington General and the National Temperance Hospitals from the board's management to that of the boards of governors of St. Mary's and University College Hospitals respectively, and the transfer of New End Hospital, Hampstead, and Coppetts Wood Hospital, Hornsey, to the control of the Royal Free Hospital board of governors.

Royal College of Surgeons of Edinburgh

At a dinner held in the Royal College of Surgeons of Edinburgh on 11 November in connexion with the opening of the Lister Institute of Postgraduate Medical Education and Research earlier in the day (see *B.M.J.*, 18 November, p. 430) diplomas of Honorary Fellowship were presented to LORD FLOREY OF ADELAIDE, Provost of Queen's College, Oxford, and Chancellor of the National University of Australia, and to Professor MICHAEL M. SWANN, Principal and Vice-Chancellor of the University of Edinburgh.

Royal College of General Practitioners

The annual dinner of the Royal College of General Practitioners was held in London on 17 November. The toast of the College was proposed by the Rt. Hon. KENNETH ROBINSON, M.P., and replied to by Dr. ANNIS GILLIE. The Guests were proposed by Dr. H. N. LEVITT and replied to by LADY STOCKS.

Heberden Society

With its president, Dr. OSWALD SAVAGE, in the chair, the Heberden Society held its annual dinner at the Royal College of Physicians on 17 November. The dinner was attended by a sizable contingent of members of the Ligue Française contre le Rhumatisme with their wives. Proposing the society's toast, Sir MAX ROSENHEIM P.R.C.P., said that the Royal College of Physicians had emphasized the need for all district hospitals to have facilities for rheumatology. Dr. SAVAGE replied for the society and afterwards presented the Heberden medal. The toast of the guests was proposed by Dr. J. A. COSH, and Dr. P. ORDONNEAU, president of the Ligue, replied. Afterwards Dr. J. P. D. MOUNSEY, speaking in French, gave the visitors a short history of the College.

British Tay-Sachs Foundation

An organization has been set up to provide funds for research into Tay-Sachs disease and other allied storage conditions. Laboratory accommodation is being made available at the Hospital for Sick Children, Great Ormond Street, London W.C.1.

Anti-smoking Education Campaign

A new organization, the British Anti-Smoking Education Society (6 Coptic Street, London W.C.1), has been formed by a group of doctors to promote research into cigarette habituation. It also plans to establish a continuing programme of popular education giving the latest data on the effects of smoking on health. Other major aims include the banning of cigarette advertising and of smoking in public places. A pamphlet

initiating the campaign and inviting financial support is being sent to doctors throughout the country. Dr. J. L. BURN, medical officer of health for Salford, is president of the society. The treasurer is Mr. T. W. HURST, secretary and treasurer of Edinburgh Royal Infirmary.

Disabled at Work

Remploy Ltd., the Government-subsidized company that employs the severely disabled, now runs 87 factories in all parts of England, Scotland, and Wales. Last year it provided work for 6,852 people. According to the chairman's annual report 24% suffered from injuries and diseases of the head, trunk, and limbs; 17% from diseases of the lungs, including tuberculosis; 21% from mental and nervous disorders; and 10% from epilepsy. The company has temporarily suspended recruitment as a result of the Government's deflationary measures. Sales for the year ended March totalled £7,790,000, an increase of £72,000.

Monopoly Inquiry

Revised terms of reference, announced on 13 November by Mr. ANTHONY CROSLAND, President of the Board of Trade, confer wider powers on the Monopolies Commission in its investigation of restrictive practices affecting professional services (see *B.M.J.*, 11 February, p. 376). They enable the Commission to examine practices authorized by or under Royal Charter, or authorized by or under any statute enacted before 1 January 1956. The Board's original request, made on 30 January, excluded the investigation of practices expressly authorized by or under any enactment or Royal Charter.

People in the News

► Professor A. C. P. CAMPBELL has been reappointed dean (part-time) of the medical school at Manchester University from 1 January to 31 December 1968.

► Professor HENRY MILLER has succeeded the late Dr. HUGH GARLAND as chairman of the medical panel of the Multiple Sclerosis Society of Great Britain and Northern Ireland.

News in Brief

After 1 January 1969 all candidates for membership of the Australian College of General Practitioners will be required to take the examination of the College. The examination for membership is at present optional.

Grants and Awards

Research grants for 1967 totalling £243,198 have been announced by the National Fund for Research into Crippling Diseases.

Recent Publications

Notes on the Mental Health Act, 1959, by CECIL W. FRENCH, chief mental welfare officer to the Bedfordshire County Council: Shaw and Sons Ltd., 7-9 Fetter Lane, Fleet Street, London E.C.4, price 2s. (by post 2s. 6d.).

Taxation and Welfare, by ARTHUR SELDON, a research monograph, published by the Institute of Economic Affairs, Eaton House, 66a Eaton Square, London S.W.1, 7s. 6d.

Programmes in the Health Sciences, a bibliography of published self-instructional material for dental, medical, and nursing students. Copies can be ordered from the Secretary, National Centre for Programmed Learning, Birmingham University, 10s. (by post 10s. 6d.).

Revised edition of *A Symposium on the Role of Fluoride in Preventive Dentistry*, with references and select bibliography. Prepared by

the Oral Hygiene Service, P.O. Box 1DY, Hesketh House, Portman Square, London W.1.

The November issue of the magazine *World Health* is in the form of an illustrated calendar for 1968, W.H.O.'s 20th anniversary year. H.M.S.O., 3s. 6d. (postage 6d.).

Coming Events

Postgraduate Medicine, 1967 (T.V. Programme).—"Intrauterine Growth," Scottish Television, 27 November (11.50 p.m.), repeat 29 November (1.10 p.m.). "Advances in Therapy," Tyne Tees Television, 28 November (1.15 p.m.), repeat 3 December (10.15 a.m.).

Royal College of Physicians of London.—Christmas lectures for young people: "What it Takes to be a Doctor," by Dr. JOHN ANDERSON, 4 January, 3.30 p.m.; "The Breeding of Butterflies and Moths as a Background to Some Medical Research," by Dr. C. A. CLARKE, 9 January, 3.30 p.m. Applications by 1 December to Secretary, R.C.P., 11 St. Andrew's Place, Regent's Park, London N.W.1.

King Edward's Hospital Fund for London.—Conference, "Building and Environmental Services for Hospital Laboratories," 13 December, Hospital Centre, 24 Nutford Place, London W.1. Fee £1 (including lunch and tea). Applications by 4 December.

British Medical Association and Institute of Mathematics and its Applications.—Joint symposium on mathematical and computer methods in medicine, 6 December, 10.30 a.m., B.M.A. House. Registration fee 15s. (members), £2 (non-members). Fee includes hamper lunch and tea. Registration forms from Secretary, British Medical Association, Tavistock Square, London W.C.1.

Symposium on Blood Diseases for Consultants and Registrars.—7 December, Lewisham Hospital, London S.E.13. Details from Dr. J. S. STAFFURTH, Lewisham Hospital.

University of Cambridge School of Clinical Research and Postgraduate Medical Teaching.—Introductory course on the biology of skin, 11–16 December, Churchill College. Details and registration forms from Secretary, Cambridge University Medical School, Tennis Court Road, Cambridge.

Societies and Lectures

For attending lectures marked Ⓢ a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Monday, 27 November

CAMBRIDGE SOCIETY FOR THE STUDY OF COMPARATIVE MEDICINE.—At School of Veterinary Medicine, 8 p.m., Professor I. H. Mills: Physiological Aspects of Renal Disease.

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 5.30 p.m., clinical meeting.

INSTITUTE OF DISEASES OF THE CHEST.—6.15 p.m., Dr. B. Strickland: The Deceptive Chest X-ray.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., combined staff consultation clinical meeting.

KINGSTON-UPON-THAMES MEDICAL CENTRE.—5.15 p.m., Dr. W. R. G. Thomas: Mycoplasma; 6.30 p.m., Dr. L. O. Butler: Mode of Action of Antibiotics.

MANCHESTER MEDICAL SOCIETY: SECTION OF GENERAL PRACTICE.—At Large Anatomy Theatre, Manchester University Medical School, 9 p.m.,

Professor Keith Simpson: What To Do With a Dead Body.

MANCHESTER MEDICAL SOCIETY: SECTION OF ODONTOLOGY.—At Lecture Room, Dental Hospital, 5.30 p.m., Professor I. Möller (Denmark): Topical Application of Fluorides.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Professor T. A. J. Prankerd: Chemical Factors in Haemolytic Anaemia.

SCOTTISH TELEVISION LTD.—11.45 p.m., Intrauterine Growth. (Sponsored by Glasgow Postgraduate Medical Board.)

Tuesday, 28 November

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Dr. V. Eisen: Kinin Formation in Human Disease.

HACKNEY HOSPITAL POSTGRADUATE INSTITUTE.—At Nurses' Classroom, 8.45 p.m., Professor W. Linford Rees: Schizophrenia.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Hammersmith Hospital, 3 p.m., Dr. W. B. Robertson: Physiological Changes and Pathological Lesions in the Spiral Arteries.

LONDON UNIVERSITY.—At University College, 5.30 p.m., special university lecture in genetics—I by Dr. S. Brenner: Genetic Aspects of the Code.

NEATH POSTGRADUATE MEDICAL CENTRE.—At Neath General Hospital, 4 p.m., Dr. J. N. Harris-Jones: Diagnosis of Thyroid Disorders.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—4 p.m., Mr. A. G. Cox: Surgical Aspects of Malabsorption.

ROYAL STATISTICAL SOCIETY.—At Manson Theatre, London School of Hygiene and Tropical Medicine, 5 p.m., Dr. A. E. Bennett: Population Studies in Lambeth.

Wednesday, 29 November

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 12 noon, surgical meeting.

INSTITUTE OF DERMATOLOGY.—4.30 p.m., Professor C. D. Calnan: The Sebaceous Gland.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. N. R. Barrett: Oesophageal Hernia.

INSTITUTE OF NEUROLOGY.—6 p.m., Mr. V. Logue, and 7 p.m., Dr. H. Davison: Cerebrospinal Fluid—Hydrocephalus and Mechanics.

INSTITUTE OF UROLOGY.—5 p.m., Mr. R. T. Turner-Warwick: Urethral Stricture.

OXFORD UNIVERSITY MEDICAL SCHOOL.—At Nuffield Maternity Home Lecture Theatre, Radcliffe Infirmary, 5 p.m., Dr. E. Gordon Smith and Dr. J. Holt: Changes in the Retina in Diseases of the Blood.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—5 p.m., Sir James Young Simpson memorial lecture by Professor T. C. Gray: Dilectus Suis Somnum.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 11.45 a.m., clinicopathological conference by Professor H. Miller, Professor K. Weinbren. (2) 2 p.m., Professor L. G. Whitby: Well Population Screening.

SCOTTISH TELEVISION LTD.—1 p.m., Intrauterine Growth. (Sponsored by Glasgow Postgraduate Medical Board.)

STORIE MANDEVILLE HOSPITAL.—(1) 12.15 p.m., Dr. G. D. Hadley: Recent Advances in Gastric Diagnosis. (2) 6 p.m., Group Captain R. Mortimer: Worms.

WEST MIDDLESEX HOSPITAL.—At Lecture Theatre, 5 p.m., Dr. A. M. Dawson: Disturbances of Carbohydrate Absorption in Man.

WHITTINGTON HOSPITAL.—At Academic Centre, Archway Wing, London N., 11.30 a.m., Professor H. E. de Wardener: Calcium Metabolism in Chronic Renal Failure.

Thursday, 30 November

ABERDEEN UNIVERSITY FACULTY OF MEDICINE.—At Large Lecture Theatre, University Medical Buildings, Foresterhill, 5 p.m., Dr. M. F. Oliver: Intensive Coronary-care Units.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Kennedy Lecture Theatre, Institute of Child Health, 5.30 p.m., Dr. D. A. Price Evans: Genetic Factors in Drug Therapy.

DUNDEE UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Dr. P. D. Griffiths: Creatine Kinase in Clinical Medicine.

FACULTY OF HOMOEOPATHY.—5 p.m., Dr. Mary Y. McA. Stevenson: Comments on Foods and Related Homoeopathic Remedies.

KINGSTON-UPON-THAMES MEDICAL CENTRE.—2.30 p.m., film, with discussion by Dr. B. W. Meade and Dr. F. R. Ellis: Long-term Care after Partial Gastrectomy.

LIVERPOOL UNIVERSITY MEDICAL STUDENTS SOCIETY.—At Anatomy Building, Surgery Lecture Theatre, Old Medical School, 5.15 p.m., B.M.A. lecture by Professor A. W. Kay: Surgical Lessons on Diarrhoea.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At 11 Chandos Street, London W., 8.15 p.m., Dr. M. H. Lessof: Immune and Autoimmune Disorders.

ROYAL FREE HOSPITAL.—5.15 p.m., Dr. I. A. Sewell: An Experimental Approach to Circulation in the Tissues.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 4 p.m., Mr. W. P. Cleland: Management of Chest Injuries. (2) 5 p.m., lecture on medical

history by Dr. E. S. Clarke: History of Microbiology.

ROYAL STATISTICAL SOCIETY: SHEFFIELD GROUP.—At Hicks Building, Sheffield University, 7 p.m., Professor D. J. Newell: Problems in Estimating the Demand for Hospital Beds.

RUNWELL HOSPITAL.—At Wickford, Essex, 8 p.m., Dr. J. W. Mack: Research into Response to Anti-depressant Drugs.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Aleck Bourne lecture by Professor J. D. Martin (Perth, W. Australia): Retarded Intrauterine Growth of the Fetus.

WESTMINSTER MEDICAL SCHOOL.—At Keene Lecture Theatre, (1) 5.15 p.m., surgical conference by Lieutenant-Colonel S. H. Janikoun: Surgery in the Far East; (2) 6.45 p.m., Dr. C. M. Conway: Comparative Studies into the Haemodynamic Effects of Some Intravenous Anaesthetic Agents.

Friday, 1 December

BROOK GENERAL HOSPITAL.—5.30 p.m., Dr. P. Blackledge: Treatment of Meningitis.

KENT POSTGRADUATE MEDICAL CENTRE AT CANTERBURY.—At Kent and Canterbury Hospital, 8 p.m., scientific lecture on man and his environment by Dr. W. R. S. Doll, F.R.S.: Environmental Cancer.

LONDON UNIVERSITY.—At University College, 5.30 p.m., special university lecture in genetics—II by Dr. S. Brenner: Genetics of Regulation in Bacteria.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—5.30 p.m., clinicopathological conference with cases from St. Thomas's Hospital.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—(1) 12 noon, Mitchell lecture by Dr. N. Lloyd Rusby: Pulmonary Tuberculosis—Present Management and Future Prospects; (2) 5 p.m., Oliver Sharpey lecture by Dr. R. W. D. Turner: Controversial Aspects of Rheumatic Heart Disease.

ROYAL POSTGRADUATE MEDICAL SCHOOL.—(1) 10.15 a.m., The Forward Look in Operating-theatre Design. (2) 4 p.m., lecture by Professor A. S. V. Burgen.

WEST MIDDLESEX HOSPITAL.—4 p.m., Dr. G. I. M. Swyer: Sex Hormone Therapy.

Sunday, 3 December

EDGEWARE POSTGRADUATE MEDICAL SOCIETY.—At Edgware General Hospital, 10.30 a.m., Professor M. D. Milne: New Concepts of Glomerulonephritis.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—10.15 a.m., seminar for general practitioners by Mr. A. Radcliffe.

ROYAL COLLEGE OF GENERAL PRACTITIONERS: EAST ANGLIA FACULTY.—At Dukes Head Hotel, King's Lynn, 10 a.m., symposium: Practical Aspects of Abortion Law Reform.

Appointments

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—A. N. Cruickshank, M.R.C.S., F.F.A.R.C.S. (consultant anaesthetist, Ipswich group of hospitals); J. M. Collis, M.B., F.F.A.R.C.S. (consultant anaesthetist, Papworth and Addenbrooke's hospitals); Cicely Pepler, M.B., F.R.C.S. (consultant orthopaedic surgeon, Norwich, Lowestoft, and Great Yarmouth group of hospitals); J. S. R. Baxter, M.B., F.R.C.S. (consultant B.N.T. surgeon, King's Lynn, Wisbech, and Duddington areas).

KING'S COLLEGE HOSPITAL, Denmark Hill, London S.E.—M. Harris, M.B., F.D.S.R.C.S., G. H. Forman, M.B., F.D.S.R.C.S. (consultants in dental surgery); D. A. Packham, M.B., F.R.C.S. (consultant urological surgeon).

MINISTRY OF OVERSEAS DEVELOPMENT.—J. L. Craven, M.D., F.R.C.S. (senior registrar in Uganda).

NORTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—N. N. Jaswon, M.D., M.C.Path. (consultant pathologist to Forest group of hospitals); H. L. Young, M.B. (medical assistant in B.N.T. surgery to Ilford and District group of hospitals).

NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—R. A. Haddow, M.B., M.R.C.P.Ed., F.F.R. (consultant radiologist at Barnet General Hospital); Eva Hamik, M.D., F.F.A.R.C.S. (consultant anaesthetist at Central Middlesex, Acton, and Neasden Hospitals); E. D. R. Campbell, B.M., M.R.C.P., D.Phys.Med. (consultant in physical medicine at Cell Barnes Hospital); U. B. H. Baruch, M.D., D.P.M. (consultant psychiatrist at St. Bernard's Hospital and Ashford Hospital).

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—C. B. Hobbs, M.B., M.C.Path. (consultant chemical pathologist, Bath clinical area); J. J. Kelly, M.B., F.R.C.S.Ed. (consultant orthopaedic surgeon, North Gloucestershire clinical area); M. A. Voyce, M.B., M.R.C.P.Ed., D.C.H. (consultant paediatrician, West Cornwall clinical area); Eileen M. Welcher, M.B., F.F.A.R.C.S. (consultant anaesthetist, Devon and Exeter clinical area (Torquay)).

TURNER-WARWICK, R. T., D.M., M.Ch., F.R.C.S. (visiting honorary consultant urologist to King Edward VII Memorial Hospital, Bermuda).

UNITED MANCHESTER HOSPITALS.—G. Howitt, M.D., M.R.C.P. (consultant cardiologist with a special interest in cardiac physiology).

Universities and Colleges

CAMBRIDGE

M.CHIR.—I. D. Hunter-Craig.
M.B., B.CHIR.—M. T. C. Mower.
M.B.—C. H. Gallimore, *S. R. Bloom, J. F. Gordon, D. I. Johnston, D. R. Tant, *D. G. Garden.

*By proxy.

GLASGOW

M.D.—J. Guthrie (with commendation).
Ph.D.—In the Faculty of Medicine: C. G. Pierrepont.

ABERDEEN

Appointments.—Dr. F. Walker, Dr. F. L. Archer, (senior lecturers, Department of Pathology); Dr. O. A. Haugen (lecturer, Department of Pathology); Mr. W. H. H. Garvie (senior lecturer, Department of Surgery); Dr. Mary B. Hector (part-time lecturer, Department of Pathology); Dr. M. H. Wittenborg (visiting fellow, Department of Anatomy); Professor B. M. V. Shetty (visiting fellow, Department of Pathology); Dr. A. K. Webster (terminable lecturer, Department of Pathology); Dr. Violet Anderson (assistant medical officer, Student Health Service).

EDINBURGH

Ph.D.—In the Faculty of Medicine: *A. Q. S. Bukhari, *E. S. G. Hettiaratchi, I. M. Negm, A. Omer, *C. Vejbæysa.
M.B., Ch.B.—D. S. Gordon, S. MacG. Hall, I. W. Young.

DIPLOMA IN MEDICAL RADIODIAGNOSIS.—A. P. Argyropoulos, E. R. Jay, G. E. Mylne.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—M. O. Akindele, R. L. Cundall, A. W. Kushner, S. K. Littmann, J. Oluwole.

*In absentia.

Appointments.—Drs. J. Bedel, E. W. J. Cameron, A. G. S. Tulloch, J. M. Monaghan, N. H. Hills, G. S. Watson (temporary demonstrators, Department of Anatomy); Dr. J. Wilson (lecturer, Department of Dental Surgery); Dr. L. I. Zander (lecturer, Department of General Practice); Dr. P. W. Brunt (temporary lecturer, Department of Medicine (Western General Hospital)); Dr. J. P. A. McManus (senior lecturer, Department of Medicine (Western General Hospital)); Dr. W. H. Price (half-time lecturer, Department of Medicine (Western General Hospital)); Mr. F. R. Clark (part-time lecturer, Department of Obstetrics and Gynaecology); Drs. Helen L. Cameron and D. Smith (part-time lecturers, Department of Orthopaedic Surgery); Miss Ruth Wynne-Davies (senior lecturer, Department of Orthopaedic Surgery); Dr. R. M. Milne (lecturer, Department of Pathology); Dr. E. S. Johnson (lecturer, Department of Pharmacology); Dr. R. M. Watt (demonstrator, Department of Physiology); Dr. R. C. Burgess (part-time lecturer, Department of Social Medicine); Mr. J. G. Clark (lecturer, Department of Surgical Science).

LONDON

The following have been appointed or re-appointed as representatives on schools of the University indicated in parentheses: Dr. C. F. Harris (Board of Management of London School of Hygiene and Tropical Medicine); Professor W. J. Hamilton (council of Royal Veterinary College); Dr. C. F. Harris (Council of School of Pharmacy).

Dr. J. R. May has been appointed to the readership in bacteriology tenable at the Institute of Diseases of the Chest.

Dr. P. Trexler has been appointed to the readership in veterinary gnotobiotics tenable at the Royal Veterinary College.

The following have been appointed recognized teachers of the University in the subjects indicated in parentheses: *Imperial College of Science and Technology*, Dr. C. G. Caro (experimental medicine); *Charing Cross Hospital Medical School*, Dr. R. E. W. B. Comerford, Dr. T. B. L. Roberts (anaesthetics). *King's College Hospital Medical School*, Dr. J. W. Laws (diagnostic radiology); Dr. V. Parsons (medicine); Dr. D. E. H. Tee (experimental pathology); Dr. K. J. Zilkha (neurology). *Royal Free Hospital School of Medicine*, Dr. I. A. D. Bouchier (medicine). *St. George's Hospital Medical School*, Dr. K. C. Carstairs (pathology (haematology)); Dr. H. J. W. Cleeve (chemical pathology); Dr. J. N. Harcourt-Webster (pathology); Dr. I. H. Kerr (diagnostic radiology); Dr. P. B. Storey (psychiatry); Mr. K. W. Wilkinson (sur-

gery). *St. Thomas's Hospital Medical School*, Dr. M. A. Barraclough (medicine); Dr. F. J. Imms, Dr. M. T. Jones (physiology). *University College Hospital Medical School*, Dr. C. J. Edmonds, Dr. A. N. Exton-Smith (medicine); Dr. G. M. Stern (neurology); Dr. H. H. O. Wolff (psychiatry). *Westminster Medical School*, Dr. S. Feldman (anaesthetics); Dr. J. B. MacGillivray (pathology); Dr. J. K. Oates (venereal diseases). *Royal Postgraduate Medical School*, Dr. E. D. Williams (pathology).

The Hazely Clifford postgraduate studentship for 1967-8 has been awarded to Dr. Daphne A. Roe.

The Mary Scharlieb research studentship for 1967-8 has been re-awarded to Mr. S. J. Lam.

The A. H. Bygott scholarship for 1967-8 has been awarded to Dr. Elizabeth S. Harper.

M.D.—A. D. F. Hurdle, J. C. Crawhall.
Ph.D.—In the Faculty of Medicine: R. C. D. W. D. Bandaranayake, M. A.-R. Moustafa, A. K. G. Nasser, A. Skarbek, G. T. Tucker, L. S. Wiggart.

The following candidate at the London School of Hygiene and Tropical Medicine has been approved at the examination indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN TROPICAL PUBLIC HEALTH.—M. I. Fazal.

MANCHESTER

Appointment.—Mr. N. H. Mahindrakar (lecturer in otolaryngology); Dr. P. G. Lynch (lecturer in neuropathology); Dr. G. B. W. Tait (lecturer, clinical section of Rheumatism Research Centre).

WALES

WELSH NATIONAL SCHOOL OF MEDICINE
Appointments.—Mr. A. H. B. de Bono (lecturer in surgery); Dr. D. K. Peters (lecturer in medicine); Dr. C. J. Roberts (lecturer in social medicine).

BIRMINGHAM

The title of university clinical lecturer has been conferred on Dr. S. P. Singh, consultant cardiologist to the United Birmingham Hospitals and to the Birmingham Regional Hospital Board.

The following have been appointed honorary postgraduate clinical tutors: Dr. B. H. Bass, Good Hope Hospital, Sutton Coldfield; Mr. H. Roberts, for the Maternity and Women's Hospitals, Birmingham.

The title of assistant clinical tutor in the Department indicated in parentheses has been conferred on the following for the period of their service in the United Birmingham Hospitals: Dr. R. Cockel (medicine); Dr. J. D. Goode, Dr. G. Hall-Davies, and Mr. W. J. C. C. Rich (rheumatology); Dr. D. Riddoch (neurology); Mr. K. M. Simpson (surgery); Dr. R. A. Thompson, Dr. J. E. J. Yates (immunology).

The title of honorary research fellow has been conferred on the following for the period of their work in the university: Dr. J. A. Kiernan, who has been awarded a junior research fellowship by the Medical Research Council, tenable in the Department of Anatomy; Dr. J. F. Harrison, consultant physician at the Selly Oak Hospital who is working with Dr. J. D. Blainey in the Department of Experimental Pathology; Dr. T. A. Betts, who is working in the Department of Psychiatry, on problems of epilepsy.

Appointments.—Dr. M. J. Andrews, Dr. J. E. D. MacLaren, Dr. M. J. McMahon (temporary lecturers, Department of Anatomy); Dr. G. Harris (lecturer, Department of Experimental Pathology); Dr. P. J. K. Maskery (acting first assistant to the professor of obstetrics and gynaecology); Dr. N. Williamson (lecturer, Department of Experimental Pathology).

NOTTINGHAM

Appointments.—Dr. D. Hopwood (senior lecturer, Department of Human Morphology); Dr. P. H. Fentem (senior lecturer, Department of Physiology).

SHEFFIELD

Appointments.—Dr. D. A. Aitken (part-time clinical teacher in obstetrics and gynaecology); Dr. Gwendoline R. Barer (part-time lecturer in medicine); Dr. E. G. Oram (part-time honorary postgraduate clinical tutor (Nottinghamshire)); Dr. J. Pullar (lecturer in Student Health Service); Dr. J. Flynn (lecturer in medical microbiology).

ROYAL COLLEGE OF PHYSICIANS OF
EDINBURGH

At the quarterly meeting of the College held on 7 November 1967, the following were elected members of the College:

J. D. Dow, A. D. Forrest, I. I. Abu-Sabra, J. G. Reid, S. K. Mandal, A. Ashraf, S. K. Roy, R. Prasad, A. H. Barlas, D. M. Morgan, P. M. Barnes, S. Hazra, T. Kumarasamy, M. O. El Motasim, A. M. Hazell, S. Agarwala, S. K. Mukherjee, M. Nuruzzaman, M. A. Menon, R. Rao, M. B. Gharipour, D. V. Khare, D. L. Singh, A. Jamil, S. Mitra, C. Y. Yeung, D. P. Jham, N. Kethari, A. Ahmad, N. Arumugam, G. A. Noori, J. M. Wilner, T. O. Cole, A. J. Gordon, A. F. B. Mabadeje, P. A. Berger, R. J. Purvis.

ROYAL COLLEGE OF GENERAL
PRACTITIONERS

At the Annual General Meeting of the College held on 18 November, Dr. John H. Hunt was elected President. At the first meeting of the new Council Dr. G. Swift was elected Chairman, Dr. J. A. R. Lawson Vice-chairman, and Dr. J. Owen Deputy Vice-chairman. Dr. B. C. S. Slater was re-elected Hon. Secretary and Dr. S. Carne was re-elected Hon. Treasurer.

At the Annual General Meeting Professor J. C. van Es, of the Institute of General Practice in Utrecht, was elected an Honorary Fellow.

Dr. E. V. Kuenssberg was awarded the Foundation Council Award.

The following were elected as the first Fellows of the College.

United Kingdom: S. I. Abrahams, C. D. Baker, H. G. Barnes, C. H. D. Bartley, L. W. Batten, F. A. Bevan, A. Brown, J. F. Burdon, R. C. Durton, P. S. Byrne, L. S. Calvert, F. S. Catto, J. G. R. Clarke, J. M. Clow, S. N. Cole, J. Cottrell, R. Cove-Smith, J. D. Craig, D. Crombie, T. L. Dowell, T. S. Eimerl, H. H. Elder, S. Freeman, D. G. French, J. Fry, E. Gancz, W. S. Gardner, R. G. Gibson, N. D. Gofton, D. G. Gordon, J. H. Grove-White, N. Guest-Gornall, B. Halfpenny, J. M. Henderson, E. B. Hickson, E. G. Housden, W. V. Howells, J. H. Hunt, W. H. Hyllton, W. F. Jones, P. G. S. Kennedy, E. V. Kuenssberg, A. Lamont, L. Lamont, J. A. R. Lawson, F. H. Lee, H. N. Levitt, G. S. R. Little, Freda M. Lucas, R. M. S. McConaghey, G. L. McCulloch, T. S. MacDonald, W. S. Macgowan, M. Marcus, J. G. Ollerenshaw, J. M. Parry, D. Peebles Brown, R. A. B. Rorie, J. Sanctuary, I. M. Scott, R. A. Murray Scott, R. Scott, A. Smith, G. Swap, G. Swift, W. G. Tait, Lord Taylor, G. I. Watson, C. A. H. Watts, D. G. Wilson, F. B. Winfield; Ireland: A. S. Boyd, J. C. C. Crawford, V. G. Doyle, S. Flannery, F. Fleetwood, K. Forsythe, I. Hooper, J. M. Hunter, J. P. Little, G. Maguire, R. P. Maybin, E. J. O'Brien, R. A. M. B. Simpson, J. C. Walsh, N. D. Wright; New Zealand: A. Aitken, A. Borrie, W. H. Brockett, D. C. Campbell, T. Childs, W. N. Clay, P. Delaney, D. J. A. Gallagher, M. Kronfeld, W. R. Lang, J. D. Lough, E. J. Marshall, C. L. E. L. Sheppard, R. P. Tuckey, H. E. S. Williams, T. K. Williams; Australia: H. S. Patterson; South Africa: F. E. Hofmeyer, N. Levy, W. A. M. Miller; Kenya: T. Hedley White, R. H. Wiseman.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: *Atitology*, London W.C.1. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.

ADVERTISEMENTS AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

Jaundice of Pregnancy

Obstructive cholestatic jaundice appearing in the last trimester of pregnancy has been called idiopathic hepatopathy of pregnancy,¹ *hépatite bénigne de la grossesse*,² and idiopathic jaundice of pregnancy.³ Perhaps recurrent intrahepatic cholestatic jaundice of pregnancy is the most appropriate term.^{4 5}

Many patients experiencing generalized itching in the last weeks of pregnancy may be suffering from this condition, for jaundice is rarely deep and may be inapparent. So the physician should seek evidence of dark urine and pale stools. After delivery pruritus ceases, and in one to two weeks the jaundice disappears. The condition is apt to recur in subsequent pregnancies.

The serum shows an increase in conjugated bilirubin and alkaline phosphatase. Serum transaminase levels are normal or slightly increased, but occasionally very high values are found. Needle biopsy of the liver shows mild focal and irregular bile stasis. Hepatocellular necrosis and cellular reaction are absent. Electron-microscopy shows the dilatation, blunting, and swelling of the microvilli which is constantly found in all forms of cholestasis.⁶ The jaundice is probably due to an unusual cholestatic reaction to a steroid produced in pregnancy. Whether this is an unusual response to a natural steroid or caused by the production of an unknown cholestatic steroid remains uncertain. Changes in oestrogen metabolism are more likely to be secondary to the jaundice and the circulation of oestrogens in the liver than a primary defect.⁷

Normal women in the last trimester show increased difficulty in transfer of the test substance bromsulphalein into the biliary canaliculi. Bilirubin is in many ways analogous to bromsulphalein, and the response in recurrent cholestatic jaundice of pregnancy may be an exaggeration of the normal one. Moreover, natural oestrogens in large doses also cause abnormalities in the transfer of bromsulphalein.⁸ There is also an association between jaundice after administration of an oral contraceptive and the intrahepatic cholestasis of pregnancy. About 100 cases of jaundice from oral contraceptives have been reported. In the largest series, 50 Chilean patients, the clinical, biochemical, and microscopical findings bore a strong resemblance to those of cholestatic jaundice of pregnancy.⁹ Forty of these 50 patients had previously been pregnant, during which 17 had suffered jaundice and pruritus and ten late pruritus only. Oral contraceptives cause a fall in bromsulphalein transport when given to normal non-pregnant women,¹⁰ and they may produce the histological appearances of intrahepatic cholestasis.¹¹ A familial incidence has been reported in relation to one patient who was affected by recurrent intrahepatic cholestasis of pregnancy and who developed cholestasis when given an oral contraceptive.¹² Her mother and her sister also suffered pruritus and jaundice in pregnancy. It is interesting that reports of jaundice after oral contraceptives come from such regions as Chile and Scandinavia, where recurrent intrahepatic cholestasis of pregnancy is also common.^{9 13}

Oral contraceptives should not be given to patients who have previously suffered pruritus in pregnancy, and special care in the prescribing of them should be taken in countries where intrahepatic cholestatic jaundice of pregnancy is frequent.

In a woman's first pregnancy the differential diagnosis of idiopathic cholestatic jaundice from viral hepatitis and other conditions causing jaundice may be difficult. It might be possible to perform a diagnostic test after delivery. Serial serum-bilirubin, alkaline-phosphatase, and bromsulphalein tests are done before, during, and at the end of a one-cycle course of an oral contraceptive drug in standard dosage. Increasing cholestasis would confirm the diagnosis of intrahepatic cholestatic jaundice of pregnancy, contraindicate further use of this method of contraception, and give warning that subsequent pregnancies might be complicated by intrahepatic cholestatic jaundice. Differential diagnosis must also be made from surgical jaundice. In some cases laparotomy has been undertaken, because of the unusually long duration of jaundice and a preceding history of operation for gallstones. In a recent well-documented case report¹⁴ the liver was found not to be enlarged, but greatly dilated bile capillaries were visible on its surface. Cholangiography showed a normal appearance, and the amount of bile secreted, the secretion pressure, and its viscosity were found to be within normal limits. The patient subsequently had a normal spontaneous delivery, and the child was healthy. The aetiology of this condition is unknown, but the prognosis is nevertheless excellent. In this patient the jaundice disappeared within three weeks and hepatic histology returned to normal within three months of delivery despite the persistence of jaundice for six months of the pregnancy.

There are certainly many other causes of jaundice during pregnancy, for it has been estimated that it complicates one of every 1,500 gestations.⁴ Viral hepatitis accounts for two-fifths of cases, intrahepatic cholestasis for one-fifth, and obstruction of the common bile duct for one in 20. The acute fatty liver of the third trimester of pregnancy is a condition observed particularly in the malnourished patient with pyelonephritis treated with a tetracycline. The liver cells contain multiple fat droplets without significant necrosis or cellular infiltrate. The liver in pregnancy, when demands for protein anabolism are increased, may be more sensitive than in the non-pregnant woman to drugs which depress this function, such as the tetracyclines. The biochemical pattern is of increased serum levels of bilirubin, reduced prothrombin time, azotaemia, hyperuricaemia, and acidosis. Serum values of transaminase and alkaline phosphatase are only moderately

raised, a point of distinction from virus hepatitis. The prognosis of acute fatty liver of pregnancy is poor and there is no clear-cut course of management; caesarean section has been advocated.⁴ Corticosteroids are of no value.

Though tests of liver function in patients with toxæmia of pregnancy may give abnormal results, particularly the alkaline-phosphatase and serum-transaminase tests, jaundice is infrequent. It was present in 10 out of 90 cases of toxæmia in H. L. Sheehan's necropsy series.¹⁵ It is a grave, terminal sign of haemolysis. Histologically the liver shows periportal deposition of fibrin in the sinusoids, with haemorrhages. Centrizonal necrosis and haemorrhages reflect shock, and an inflammatory reaction is inconspicuous. In eclampsia the damage to the liver is terminal, and toxæmia of pregnancy cannot be regarded as primarily involving the liver. Toxæmia rarely enters into the differential diagnosis of jaundice in pregnancy.

Finally, drug jaundice should not be overlooked. Increased sensitivity to tetracycline has been discussed. Other drugs to be borne in mind include chlorpromazine and halothane, while the sulphonamides, novobiocin, and phenacetin should be considered as possible causes of jaundice in immature or premature babies.

Appointment Systems in General Practice

The growth of appointment systems is one symptom of the reorganization of general practice which is gathering momentum. Dr. Bruce Cardew estimates in a paper at page 542 of this week's *B.M.J.* that a third of all N.H.S. practices are now offering a complete appointment service to their patients. Thus 17,000,000 people can now consult their doctors by appointment. That the new pay system is accelerating the movement is suggested by an increase in the first nine months of this year of 2,773 in the number of doctors using the Lloyd-Hamol appointments diary, but it is noteworthy that under the Pool system 4,500 doctors had been prepared to finance appointment schemes entirely out of their own pockets.

J. M. Bevan and G. J. Draper,¹ of the Oxford University Department of Biomathematics, have recently investigated appointment systems. They had three main objectives: to find out the attitudes of doctors and patients to them; to get quantitative estimates of their effect on doctors' work load and patients' waiting time; and to determine which types of practice would find appointment systems worth while and what were the best ways of organizing them. They formed various theories from interviews with and postal surveys from doctors and patients, and tested them in an experimental study of the records of several practices before and after starting appointment systems. The vast majority of doctors and patients who had used an appointment system were satisfied with it. Nearly all doctors found that it was easy to introduce into their practices, that it evened out the work load throughout the week, and that it decreased the strain of their work and improved its quality. Patients who were elderly or of low intelligence found it difficult at first, especially if they had not been informed beforehand by circulars about its introduction and how to use it, but they liked it once they had got used to it. About half of the doctors who did not have appointment systems at the time of the survey thought them

desirable but cited overworking of existing staff as the main reason for not starting them. Most of them did not think that reimbursement of part of the cost of ancillary staff would influence this decision, though the marked increase in appointment systems since January suggests that this was a rationalization of their reluctance to take the plunge. Patients showed a similar conservatism. Their satisfaction with the status quo, noted elsewhere by Ann Cartwright,² was reflected by the far less favourable reaction to the idea of appointment systems by patients of doctors who did not have them. Once they had experienced a successful system patients were overwhelmingly in favour of it, probably because in the average practice it halved their waiting time.

In quantitative terms the degree of success of an appointment system can be measured by the proportion of patients actually making appointments and the proportion failing to keep them. These figures varied in the practices studied from 45% to 96% and from 0% to 7%, respectively. Most patients were punctual, and of the 10% who were not only a third were more than five minutes late. As Dr. Stuart Carne points out at page 544 of this week's *B.M.J.*, an appointment system can also work in a practice with a high proportion of West Indian and West African immigrants, who on the whole are not such good timekeepers as the English and Irish patients.

The success of any system depends to a large extent on the organizing ability of the receptionists and their attitude to patients. They need to be present during all surgery sessions at least, and, on average, staff time must be increased by ten to twelve hours per week per doctor in a partnership and twice as much in a single-handed practice. Success depends also on estimating beforehand the doctor's consultation time—which may differ for each doctor in a partnership—and scheduling appointments accordingly. Doctors must be punctual themselves, because patients who repeatedly have to wait long after their appointment time get disillusioned and stop making appointments.

One of the changes which would help fewer practitioners to care effectively for more patients would be an increase in the ratio of surgery consultations to home visits. The figures from the practices, admittedly small in number, which kept records before and after an appointment system did not show any such increase, though more detailed data and a more rigorous analysis would have been needed to detect any but a very large one. That a consultation probably did acquire greater significance is suggested by the fact that about a quarter of the doctors questioned thought there had been a decrease in trivial consultations and an increase in non-trivial ones. But if an appointment system does not in itself persuade patients to come to the surgery instead of asking for a home visit it is an essential prerequisite for other means of achieving that end: by having a doctor consulting throughout the day as J. S. K. Stevenson³ found; or by receptionists pointing out the convenience of a surgery attendance at a particular time for the patient himself as well as for his doctor, as Andrew Smith⁴ has suggested.

What does emerge quite clearly from the investigation is that it is worth while for every type of practice, except probably a single-handed one, to run a system in which all sessions are by appointment and all patients are encouraged to make an appointment.

Reappraisal of the Austin Flint Murmur

When Alice, in *Through the Looking-glass*, was trying to reach a particular hill she found that the only way to reach her destination was to turn her back on it and walk in the opposite direction. Something of the same kind seems to be happening to our conception of the Austin Flint murmur.

In Austin Flint's original description of the murmur¹ he suggested that the likely pathogenesis was that the mitral valve leaflets became closed in early diastole as a result of over-distension of the left ventricle from free aortic incompetence, and that during atrial systole the mitral valve reopened with accompanying vibrations of the anterior cusp, producing a characteristic blubbery murmur. Recently it has been shown that in cases of free aortic incompetence reversal of the left atrioventricular gradient takes place in late diastole, left ventricular exceeding left atrial pressure by 20 mm. Hg or more.²⁻⁴ E. D. Wigle and C. J. Labrosse⁵ in 1965 found that an Austin Flint murmur was present in 9 out of 14 patients who developed sudden severe aortic incompetence and a reversal of the left atrioventricular diastolic pressure gradient. Clearly in these cases forward flow through the mitral valve in late diastole could not play any part in the production of the murmur. The next year H. E. Aldridge and his colleagues⁶ demonstrated diastolic mitral insufficiency by cineangiography in nine patients with severe aortic incompetence and reversed pressure gradients. It remained for S. Lochaya, M. Igarashi, and A. B. Shaffer⁷ to suggest that the Austin Flint murmur commonly found in severe aortic incompetence was due to diastolic mitral incompetence. They reported three cases with cineangiographic evidence of late diastolic mitral regurgitation coinciding with an Austin Flint murmur recorded in the phonocardiogram.

Given that diastolic mitral regurgitation does indeed sometimes occur in severe cases of aortic incompetence, two further problems remain. What causes the mitral valve to become incompetent in late diastole? And are the vibrations set up by this regurgitant puff responsible for the Austin Flint murmur? Lochaya and his colleagues⁷ suggest that dilatation of the mitral valve ring due to left ventricular enlargement may result in incomplete closure of the mitral orifice by the valve cusps. The normal function of the chordae tendineae might be impaired by the great ventricular dilatation, and another factor could be partial displacement of the closed or nearly closed mitral valve cusps during the atrial systole. Whether a small puff of mitral regurgitation would be sufficient to produce a loud mitral diastolic murmur is uncertain, but it is difficult to present a satisfactory alternative explanation for the murmur in patients with a reversed diastolic atrioventricular gradient.

So the Austin Flint murmur may have a different pathogenesis in individual cases of aortic incompetence, depending on the direction of the left atrioventricular diastolic pressure gradient. When the murmur occurs with less severe aortic incompetence and without reversal of the left atrioventricular

diastolic pressure gradient the Austin Flint murmur could well be due to forward flow of blood through a functionally narrowed mitral valve, as originally suggested. In more severe cases, however, with a reversed pressure gradient, diastolic mitral incompetence seems to be a likely explanation of the pathogenesis of the murmur.

Coal Mining, Pneumoconiosis, and Lung Cancer

In 1936 N. M. Kennaway and E. L. Kennaway¹ drew attention to the low mortality from lung cancer among coal miners as compared with the general male population. Further studies by the Kennaways^{2,3} and by other workers⁴⁻⁶ led to the same conclusion; and according to the *Decennial Supplement* of the Registrar General published in 1938⁷ the standardized mortality ratio (S.M.R.) for lung cancer in men working on the coal face for the three years 1930-2 was 67 (compared with 100 for all males). The S.M.R. for lung cancer in underground workers in coal mines other than coal-face workers was lower still—namely, 36. In a more critical study conducted in South Wales W. R. L. James⁸ found lung cancer at necropsy in 5.4% of 1,531 non-miners but in only 3.3% of 1,827 coal miners. When he subdivided the miners into those with simple pneumoconiosis and those with progressive massive fibrosis (P.M.F.) the rates were 5.1% and 1.4%, respectively. More recently K. P. Goldman⁹ has analysed unpublished data collected by the Medical Research Council's Epidemiology Unit in South Wales. These data consisted of records of radiological examinations for pneumoconiosis and information on causes of death as written on death certificates for a community of 5,096 miners and ex-miners in the Rhondda Fach Valley in Glamorganshire. The results of Goldman's analysis were somewhat in conflict with the findings of James⁸: the mortality from lung cancer was highest, and equal to the national average, among miners with P.M.F., lowest in those with simple pneumoconiosis, and intermediate in those free of radiological evidence of dust disease.

Both James⁸ and R. A. Smith¹⁰ reported that survival rates are better than average in miners after surgical resection of lung cancer. Goldman¹¹ investigated this phenomenon in a careful retrospective survey of cases of primary lung cancer who attended the regional thoracic centre for South Wales between 1954 and 1960. The case material included 172 miners and 518 non-miners, and was analysed according to age, sex, smoking habits, length of time symptoms were present, respiratory function, tumour histology, method of treatment, and survival. In addition, the 172 miners were classified according to degree of pneumoconiosis as assessed radiologically. The miners as a group had a slightly reduced forced expiratory volume (F.E.V.), but differences between miners and non-miners in smoking habits, length of symptoms, average age at onset of symptoms, and spectrum of tumour types were small. Similar proportions of miners and non-miners were deemed operable, but, as noted by T. F. Nealon,¹² the immediate operative mortality was higher in the former. Survival during the five years after operation or diagnosis was similar in miners and non-miners, both for the inoperable cases and for the surgically treated cases who survived the first 28 days after operation. However, among miners, whether treated by surgery or not, survival time during the

two years after diagnosis increased with the severity of simple pneumoconiosis as determined radiologically.

It has been suggested^{10,11} that this better survival from lung cancer in the presence of pneumoconiosis may be due to the blockage of lymphatics by fibrosis and particle-laden macrophages,¹³ which serves to prevent the dissemination of cancer cells. It would be tempting to argue that the same factor could be responsible for the reduced incidence of clinically recognized lung cancers in miners, but this is unlikely in so far as Goldman found evidence of better survival from the disease only in the minority of miners with the more severe grades of simple pneumoconiosis. A mere excess of coal dust in the lungs in the absence of radiological evidence of pneumoconiosis did not affect survival time.

The difficulties of studies of this kind can scarcely be exaggerated. For instance, the diagnosis of lung cancer is rendered difficult by the presence of pneumoconiosis.^{12,14,15} A miner, particularly a pneumoconiotic, is more likely than a non-miner to be under radiological surveillance, with the result that lung cancer may be diagnosed earlier. Also one must question whether sufficient account has been taken of exposure to tobacco smoke. It is true that many workers¹⁶⁻²¹ have either failed to find much difference between miners and non-miners in relation to their smoking habits or have observed that the smoking habit is more prevalent among miners than in the general population. However, the results of three surveys¹⁷⁻¹⁹ indicated that the proportion of miners who are heavy smokers is lower than for the general population. Furthermore, according to G. F. Todd,²² though miners were smoking more than the average for all social classes in 1958, the position was reversed by 1961. An underground worker is precluded from smoking during most of his working day. The accumulated effect of these differences might be important in relation to the lowered incidence of, and better survival from, lung cancer in miners.

D. J. B. Ashley²³ has recently drawn attention to an excessive mortality from bronchitis and a reduced mortality from lung cancer in areas of England and Wales where coal mining and textile industries are prominent. He excludes the possibility that differences in exposure to general air pollutants may be responsible, but does not consider the

possible influence of differences in smoking habits. His suggestion that "the dusty lung is in a state of enhanced immunological competence and is better able to destroy the first few cells which have undergone malignant transformation than is the normal lung," though interesting, must be regarded as highly speculative. L. L. Old and his colleagues²⁴ reported that in mice B.C.G. infection non-specifically increases resistance both to isologous tumour grafts and to the induction of cancer by 3-methylcholanthrene. However, in general, the function and importance of immune mechanisms in relation to carcinogenesis are far from clear, and certainly in the present instance it would be wise to defer detailed consideration of possible mechanisms until the facts are more certain.

Foot-and-mouth Disease in Man

True foot-and-mouth disease in man is a very rare infection. During outbreaks of the disease in cattle vesicular eruptions in patients who have come into contact with infected animals naturally incur suspicion, but a diagnosis of foot-and-mouth disease confirmed by laboratory investigation is hardly ever made. Cases described have been mainly from Germany and Scandinavia, where large epizootics have been more frequent than in Britain. In 1939 A. Flaum¹ described four cases occurring during an epizootic which affected 4,300 herds of cattle in southern Sweden—a worse outbreak than that now in England, grievous though this one is. More recently W. Pilz and H. G. Garbe² have published excellent colour photographs of the hand lesions in two patients infected in the laboratory. These and nearly all previously reported cases have been due to type O virus, though one case due to type C virus has been recorded.³ Incubation periods have been from three to five days.

On page 529 in the *B.M.J.* this week a case due to type O virus in a Northumberland man is described. The signs and symptoms were similar to those in the European cases—moderate fever (up to 39.5° C. is common) preceding the eruption, inflamed throat, painful lesions on the tongue, and blisters on the hands and feet. An unusual feature, not previously described, was the recurrent crops of blisters from which no virus could be isolated. It may be that in this patient a pre-existing skin disorder may have reduced the normally very high human resistance to infection by foot-and-mouth disease virus. One of Pilz and Garbe's² patients had been subject to neurodermatitis of long standing. As in other cases, the blisters in the Northumberland man healed in a week. Also characteristically, virus in high titre was recovered from blisters, and the titres of both complement-fixing and neutralizing antibodies diminished rapidly after convalescence.

¹¹ Born, W., *Dtsch. Arztsbl.-Ärztl. Mitt.*, 1967, 64, 1703.

Human resistance is normally so high that several attempts to infect humans artificially by injecting blister fluid from animals have failed; no lesions were produced and virus could not be recovered from the volunteers' blood at any time after the injection. Subclinical infection is exceedingly rare. Antibodies have been reported in a few laboratory workers exposed over long periods to a high level of infection; in one series five workers were found to have acquired neutralizing antibodies.⁴ Only one such case is known in Britain.

Early failures to infect experimental animals from supposed cases of human foot-and-mouth disease are much more easily explained. The cases may really have been hand-foot-and-mouth disease, a not uncommon human infection first described in Britain at a time when there were numerous outbreaks of foot-and-mouth disease in cattle.⁵ This syndrome is not due to foot-and-mouth virus but is caused by a Coxsackie virus, usually type A16, occasionally A5⁶ or A10.^{7,8} The lesions differ from those of foot-and-mouth in rarely reaching 5 mm. diameter, and they never reach the size (1–2 cm. diameter) seen on hands infected with foot-and-mouth virus. In children especially, maculopapular lesions are often present on the buttocks—whence it has been suggested that a better name might be "hands, mouth, and bumps-a-daisy disease." Fever is rare; the lesions usually clear up in a week. Excellent black-and-white^{9,10} and colour¹¹ photographs have been published.

Differentiation between the two diseases is not likely to be difficult except in the early stages of the eruption. But if there is the slightest question of a human vesicular eruption infection being foot-and-mouth disease the medical officer of health should be informed and the patient should be isolated in hospital for eight days. Specimens from possible cases of human infection should not be sent to any laboratory other than the Animal Virus Research Institute at Pirbright. Both Coxsackie and foot-and-mouth viruses are easily isolated in suckling mice; and it might be all too easy for a virus as infectious to animals as foot-and-mouth to escape from a laboratory less well designed to contain it than that at Pirbright. The Pirbright laboratory staff must be working overtime at present; nevertheless, a fresh case of human infection, should one occur, might well repay investigation. None of the published descriptions mention, for example, whether virus is excreted in the urine or faeces and if so for how long. It might be important to know this.

Intestinal Absorption

The intestine has been turned inside out and back to front in order to understand the physiology of intestinal function. More recently a series of new techniques—electron microscopy, histochemistry, autoradiography, radioisotopes, chromatography—have been adapted to the investigation of the structure and function of the intestinal epithelial cell. D. H. Smyth¹ has aptly described the life of this remarkable cell as a short and merry one, if merriment is the equivalent, in cellular terms, of a range of activities possessed by few other cells in the body. Its life is brief, for the epithelial lining of the intestine is renewed every few days.

This and related topics of intestinal absorption are well reviewed in a recent *British Medical Bulletin*. Histochemical techniques have proved helpful in interpreting the absorptive

¹ Smyth, D. H., *Brit. med. Bull.*, 1967, 23, 205.

defect in steatorrhoea, and in this issue A. G. E. Pearse and E. O. Riecken demonstrate beautifully the value of histochemical and cytochemical techniques in applied research, allowing us to make assumptions about the functions of particular organelles and to suggest changes in the inter-relationship between one organelle and another.

There are also chapters on the absorption of carbohydrates, proteins, fats, salt and water, vitamins, and iron, all of which are authoritative. It is exciting, too, to learn how new techniques have thrown light on the means of transfer of these products from the intestinal lumen to the blood or lymph. The absorptive capacity of the small bowel is probably not static. It has a large functional reserve, which normally is seldom required, and R. H. Dowling shows that under stress it may respond by enhancing its absorptive capacity. Increased absorption has been found after a high-bulk diet, intermittent starvation, and in malignant disease. Resection of the small bowel in man may be followed by mucosal hypertrophy and a resultant increase in the absorptive surface area. These changes were more obvious in the ileum after proximal resection than in the jejunum when the distal small bowel was removed.

Lest readers should regard this symposium as of interest to gastroenterologists only, M. D. Milne compares defects of intestinal transport with their renal counterpart, for the mechanism of absorption of some substances by the intestine is similar to that in the renal tubules. Practical clinical implications for the general physician are further expanded by Soad Tabaqchali and C. C. Booth in reviewing the significance of intestinal flora and of the antibiotic response in patients with anatomical abnormalities. Malabsorption of vitamin B₁₂ and fat can usually be corrected within three or four days of starting treatment with a tetracycline in a patient with, say, jejunal diverticulosis. After antibiotic treatment the bacterial count in the jejunal fluid may be expected to fall, faecal fat and nitrogen become normal, absorption of vitamin B₁₂ improve, and indicanuria to be much reduced. The level of indicanuria reflects indole production in patients with a stagnant loop of bowel. Increased intestinal bacterial activity acts on the amino-acid tryptophan to produce indole. Measurement of the urinary indican may therefore be used as a gross indication of indole-producing bacteria in the gut, such as *Escherichia coli* and *Bacteroides*.

Premature Rupture of Membranes and Maternal Death

With a maternal mortality of 2.58 per 10,000 total births childbearing in Britain is now safer than ever before. The need to recognize those patients at increased risk in time to take necessary precautions has been emphasized in each Maternal Mortality Report.¹ Many recurring "avoidable factors" have been identified, but nevertheless nearly 40% of all maternal deaths are still associated with them.

It is well known that uterine sepsis can be a complication of rupture of the membranes. The identification of pathways of exogenous infection, the discovery of chemotherapeutic and antibiotic preparations, and dramatic reductions in the number of deaths from puerperal infection have contributed to a widely held but erroneous view that sepsis is no longer a serious obstetrical hazard. Its lethal role in abortion and caesarean section, particularly after prolonged labour, has

been emphasized¹ and evidence relevant to its association with premature rupture of the membranes has now been produced by G. A. Webb.² His conclusions are based on an analysis of 1,054 maternal deaths reviewed by the Maternal Mortality Committee of California. Fifty-three women died after spontaneous rupture as defined by N. J. Eastman and L. M. Hellman³: "rupture before the onset of labour." One death followed surgical induction. Eighteen died between the 16th and 30th week of gestation, ten by the 20th week. Though it is difficult to exclude interference in any abortion series cases were omitted if it was confirmed or even suspected. The ages of the women who died ranged from 18 to over 40; the highest incidence was among gravidae four-plus. Only 11 infants survived of 31 delivered after the 36th week.

Some important questions remain unanswered in Webb's paper, but there are features which merit attention. During the period of eight years premature rupture of membranes was associated with 5% of maternal deaths, and in this group sepsis was responsible in 70%. *Escherichia coli* was the most commonly identified organism; there were only three anaerobic infections, two due to streptococci and one to *Clostridium welchii*. Twenty-two women died from septic shock, but treatment led to fatal pulmonary embolism in six and acute congestive heart failure in one, emphasizing the need for constant supervision in the care of these patients.

Dangers increased with the time interval between rupture of membranes and either delivery or the onset of pyrexia, but this interval was less than 24 hours in 15 cases. Most patients were apyrexial on admission to hospital, and Webb suggests that the systemic response to uterine infection usually occurs after the onset of labour, unless infection is overwhelming. Antibiotics were given too late and in inadequate doses. A surprising feature was that seven mothers with ruptured membranes died of amniotic embolism (four were infected) and in six this followed the administration of Pitocin or Syntocinon (both oxytocin injections). The apparent association of oxytocins and embolism justifies further study.

Premature rupture of membranes precedes approximately 10% of labours. The risk of maternal death is small (Webb assesses it as one in 5,451), but the patient should be included in a high-risk category. Rupture may indicate a complication such as malpresentation, posterior position, placenta praevia, or disproportion, but should itself be regarded as an emergency requiring specialist care. Opinions differ on whether immediate antibiotic therapy is necessary, but if given it should be designed to deal with both coliform and coccal infections. Cervical culture for organisms and sensitivity is a wise precaution at the first examination and a rising pulse rate, pyrexia, hypotension, oliguria, or icterus are definite indications for intensive antibiotic treatment. If on admission the obstetrical position is otherwise favourable a carefully controlled oxytocic infusion is indicated, but if progress is unsatisfactory or if the position is unfavourable (large foetus, high head, posterior position and uneffaced cervix) caesarean section is indicated and made safer by avoiding delay.

Premature rupture of membranes should not kill the mother or the child, but the treatment which they subsequently receive may do so.

Renal Glucose Threshold Variations with Age

W. J. H. BUTTERFIELD,* M.D., F.R.C.P.; H. KEEN,* M.B., M.R.C.P.; M. J. WHICHELOW,* M.A.

Brit. med. J., 1967, 4, 505-507

Each year some millions of urine samples are examined routinely for glycosuria in hospitals, clinics, and practices to screen patients for diabetes mellitus; and many more are tested by sufferers from this condition to assist in the management of their individual cases. Such tests rightly assume that there is some relation between the concentration of glucose in the blood and that in the urine. Thus the concept of the "renal threshold for glucose," though not strictly correct from a physiological point of view, retains a practical utility in these clinical situations. Despite this, surprisingly little attention is paid to its variations in populations or to its level in individual patients. In many important texts either there is no quantitative indication of the blood-sugar significance of glycosuria (Best and Taylor, 1961; Danowski, 1964; Dunlop *et al.*, 1964) or there is a choice of values for the renal threshold quoted as 170 mg./100 ml. Loeb (1959), as 180 mg./100 ml. by Lawrence (1955), Lister (1959), and Houston *et al.* (1962), and as 200 mg./100 ml. by Ellenberg and Rifkin (1962). Peters and Van Slyke (1949), who examined this question in some detail, give the normal range as 140 to 200 mg./100 ml. It has been suggested that the renal threshold may be raised in older diabetics (Lawrence, 1955; Loeb, 1959) and that it is higher in women than in men (Steinberg, 1965), while Robertson and Gray (1953) have studied some diabetics with low renal thresholds.

With regard to the management of diabetes, Lawrence (1955) and Joslin *et al.* (1959) are among the few who emphasize the importance of establishing the renal threshold in individual cases.

So far as detecting diabetes is concerned there is a widespread realization that finding glucose in a random postprandial urine sample is far from establishing directly a diagnosis of diabetes. In most cases subsequent glucose-tolerance tests will show that the glycosuric person is not diabetic (College of Gen. Pract., 1962; Butterfield, 1964; Keen, 1964; Sharp, 1964).

In contrast to the non-diabetic glycosurics, the 1962 Bedford Survey indicated clearly that there were also many hyperglycaemic people without glycosuria in the population. The possibility that unrecognized hyperglycaemia might be an important factor in vascular disease (Keen *et al.*, 1965; Ostrander *et al.*, 1965; Kingsbury, 1966), and our clinical experience with established diabetics, in whom we found renal thresholds as low as 45 and 60 mg./100 ml. and as high as 320 mg./100 ml., stimulated us to re-examine the data about glycosuria from the Bedford Survey and consider them in terms of the detection and management of diabetes.

Definitions

Test for Glycosuria.—Clinistix (Ames Co.): the appearance of a blue colour on the test strip one minute after dipping in

the specimen shows the presence of glucose exceeding 0.1 g./100 ml.

Capillary blood sugar results two hours after 50 g. of glucose by mouth (arbitrarily divided into the following groups): normal <120 mg./100 ml.; hyperglycaemic >120 mg.; borderline diabetic 120-199 mg.; diabetic >199 mg.

Methods and Material

The subjects studied were adult citizens of Bedford not known to have any disturbance of carbohydrate metabolism. All persons on the Electoral Roll were asked to provide a specimen of post-breakfast urine and 25,701 people had their urine tested, of whom, excluding known diabetics, 4% were found to have glycosuria. These were termed the glycosurics.

An age/sex stratified random sample of 535 subjects drawn from the entire co-operating population underwent standard 50-g. oral glucose-tolerance tests. Blood sugar levels were estimated by a modification of the microferricyanide reducing method in the autoanalyser (Whicelow *et al.*, 1967) on capillary samples taken fasting and at 30, 60, 90, 120, and 150 minutes after the administration of a drink containing liquid glucose equivalent to 50 g. of dextrose monohydrate. It was possible to test for glycosuria the urine passed between 60 and 120 minutes by 295 randomly selected persons. Since the presence of any small quantity of sugar-free urine in the bladder before the glucose-tolerance test could have diluted the post-glucose glycosuria, the presence of glucose and not its concentration will be considered here. It should be pointed out, under these circumstances, that from the presence of glycosuria we can only deduce that the renal threshold was lower than the peak value found, and that in the absence of glycosuria the renal threshold was higher than the peak value.

The age/sex composition of the random sample and the subsample also tested for glycosuria are shown in Table I.

TABLE I.—Structure of the Random Sample

Age	Men		Women	
	Total	No. Tested for Glycosuria	Total	No. Tested for Glycosuria
20-29	46	25	48	26
30-39	43	23	49	25
40-49	46	27	45	25
50-59	43	35	48	23
60-69	38	20	48	37
70-79	39	25	42	27

Results

During the screening survey 4% of the population were found to have glycosuria (after breakfast) whereas 30% of the random sample subjects had glycosuria during the glucose-tolerance

70-79	7.8	52	4.5	26

test. Table II shows the percentage of subjects in each group having glycosuria at the survey and during the glucose-tolerance test. At the survey, but not during the glucose-tolerance test,

women 12 had renal thresholds below 180 mg., and six below 160 mg., while 30 had peak blood sugars above 180 mg. with no glycosuria.

Discussion

Wide Variation of Renal Threshold: High Thresholds in the Elderly

It is clear that in many individuals the renal threshold was lower than 160 mg./100 ml. or higher than 200 mg./100 ml., and that it appeared to rise with age.

The postprandial blood sugars at the survey were probably much lower than after a test glucose load (Kenny and Chute, 1953) as is indicated by the higher prevalence of glycosuria after 50 g. of glucose. The prevalence of glycosuria was much higher among men than women at the survey but less so during the glucose-tolerance test (Table II). The best explanation for these findings would be that more men have on average lower renal thresholds than women, rather than that there is any difference in the sex incidence of diabetes, or that women diabetics had been removed from the survey group through the detection of diabetes at antenatal clinics, as was thought earlier.

Recognizing Diabetics in Clinical Practice

What do the foregoing results mean to the practitioner routinely testing the patients' urine to detect diabetes? Table III shows the probability that any postprandial urine test result indicates that the patient will be hyperglycaemic (see Definitions). It will be seen that young glycosurics are unlikely to have diabetes, but that, though older people are more likely to have diabetes if they have glycosuria, the absence of glycosuria does not preclude diabetes, particularly among women. If the patients are given a 50-g. glucose drink and the urine is tested for the presence of sugar between one and two hours later, not only

will the number of false positives (persons with glycosuria and normal blood sugars) be greatly increased, but there is still a 10% chance that diabetics (see Definitions) will not have glycosuria, and that their diabetes will go undetected (Figs. 3 and 4).

TABLE III.—Probability of Diabetes in Glycosuric and Non-glycosuric Subjects

Subjects	Postprandial Glycosuria	Sex	% Likely to be Hyperglycaemic (2-hr. B.S. $\geq$ 120 mg./100 ml.)
Under 50 years	Negative	Men	7%
		Women	9%
	Positive	Men	11%
		Women	17%
50 and over	Negative	Men	15%
		Women	27%
	Positive	Men	35%
		Women	73%

FIG. 1.—Peak blood sugar levels during glucose-tolerance tests in random sample men. FIG. 2.—Peak blood sugar levels during glucose-tolerance tests in random sample women. FIG. 3.—Blood sugar levels two hours after 50 g. of glucose in random sample men. FIG. 4.—Blood sugar levels two hours after 50 g. of glucose in random sample women.

the prevalence of glycosuria rose with age in both sexes, and also was about twice as high in the men as in the women.

Figs. 1 to 4 show the peak and two-hour blood sugar levels during glucose-tolerance tests plotted against age for both sexes, indicating those subjects with and without glycosuria. The peak blood sugar (which usually occurred at 60 minutes) rose with age (Figs. 1 and 2) and there tended to be more people, especially women, who had sugar-free urine despite high blood sugar levels (over 180 mg./100 ml.) among the older age groups. There were a large number of young persons, particularly young men, with glycosuria despite low peak levels.

It will be seen from Figs. 1 and 2 that renal threshold values as low as 130 mg. and as high as 305 mg./100 ml. were found. There were 20 men with renal threshold values below 180 mg., and 9 lower than 160 mg., whereas 14 men had peak blood sugars above 180 mg. with no glycosuria (Fig. 1). Among the

Since diabetes is defined in terms of blood sugar levels (W.H.O. Expert Committee, 1965) the only satisfactory solution to the problem of diabetes detection is to measure the blood sugar level (we have found a single estimation two hours after a 50-g. oral glucose load to be the most satisfactory). This emphasizes the need to provide the general practitioner with a quick, simple, and valid blood sugar method for the diagnosis of diabetes, preferably one which can be carried out in the surgery.

Importance of Renal Threshold in Management of the Individual Diabetic

Another question of interest to every clinician, brought to light by this study, is the proper interpretation of the results of testing for glycosuria when controlling diabetics.

It is apparent from the foregoing results that the renal glucose threshold should always be established for each diabetic at diagnosis and the results of the subsequent urine tests interpreted in the light of this threshold. From Figs. 1 and 2 it can be seen that many young diabetics may have very low renal thresholds, so that to advise them to adjust their control to keep their urine sugar-free may be to keep them in perpetual danger of hypoglycaemia, as in the two supposedly uncontrollable brittle diabetics (mentioned earlier) found to have renal threshold levels of 45 and 60 mg./100 ml. Failure to realize how low it was had resulted in one of these patients being in hospital for many weeks to the "stabilized." An even greater risk lies in the possibility that the considerable urinary glucose loss may provoke carbohydrate lack and "starvation ketosis" in the diabetic. Heavy glycosuria and ketonuria may then be misinterpreted and lead to increased insulin dosage when what is required is increased carbohydrate intake.

On the other hand, elderly diabetics with sugar-free urine may, in fact, be suffering from persistently high blood sugar levels. If the threshold is elevated in such cases, it may be more sensible to use the sensitive enzyme-impregnated test papers (Clinistix or Tes-Tape) on postprandial urine samples as an index of diabetic control, rather than copper sulphate reduction system tablets (Clinitest) on samples passed before meals, as is so often the case.

Detection of Diabetes: Epidemiological Surveys

With regard to the recognition of diabetes, either in detection drives or in epidemiological surveys, it must be stressed that the presence of glycosuria is by no means diagnostic of diabetes. Only one-third of the subjects with glycosuria at the Bedford Survey were hyperglycaemic. Also, the absence of glycosuria does not preclude diabetes, as 11% of the population we studied were hyperglycaemic, of whom about 90% were non-glycosuric. Some of these non-glycosuric subjects even had two-hour blood sugars over 200 mg./100 ml. at the subsequent glucose-tolerance test. Indeed, it can be calculated from our data that in a British population the preliminary screening by use of postprandial glycosuria will fail to detect over half the diabetics at large with blood sugars over 200 mg./100 ml. at two hours during a glucose-tolerance test. We therefore have to admit that our survey, and indeed many others based simply on glycosuria, failed to detect most of the unrecognized, mainly elderly, diabetics in the community.

Of course, attempts to detect diabetes by glycosuria have been widely used in the past because the techniques are so simple compared with blood sugar estimations. Can urine testing be made a more reliable reflection of hyperglycaemia? Testing the Bedford random sample for glycosuria after the standard oral glucose load showed that the proportion of glycosurics rose from the 4% seen among the population after a random breakfast to 30%. But unfortunately this procedure too will have its limitations; Figs. 3 and 4 show that an occasional diabetic will still be missed as well as a much larger number of borderline cases (see Definitions). Attempts to

screen all members of a community with even a modified form of the glucose-tolerance test involve a heavy burden on the laboratory.

Since the renal threshold can vary so much and reach such high values in old age, earlier ideas, that of diabetes as a disease where a high blood sugar is always associated with glycosuria and dehydration, have to be abandoned. Diabetes mellitus, the "siphoning off of sweetness into the urine," is not necessarily a concomitant of hyperglycaemia. We have to recognize that hyperglycaemia often exists without glycosuria, especially in communities where the proportion of old people is high, and that since we now define diabetes in terms of hyperglycaemia it is only by tests for hyperglycaemia that we shall be able to recognize diabetes and establish its prevalence in the community.

These points will have to be carefully considered by epidemiologists before they undertake further survey work. They will need to decide how many people are to be screened and whether or not they are to be screened for glycosuria, or for hyperglycaemia. Finally, in view of the high prevalence rates of hyperglycaemia in Western communities, the organizers of detection drives will be wise to ask themselves not only about the facilities and manpower available for the survey but also for the subsequent treatment of the cases found.

Summary

The results of testing an age-sex stratified random sample of the Bedford population for glycosuria during glucose-tolerance tests showed that the renal threshold level is very variable, and increases with age, especially among women. Renal threshold values as low as 130 mg./100 ml. were found in young subjects and as high as 300 mg. in elderly subjects. Thirty per cent. of this random sample had glycosuria during the glucose-tolerance test compared with only 4% when tested after breakfast. These findings are discussed in relation to the management of diabetic patients and the planning and execution of diabetes detection surveys.

We wish to acknowledge our thanks to the staffs of the Public Health Department, Bedford, and the Department of Experimental Medicine, Guy's Hospital, who collected and tested the urine samples, and to the Ames Company for supplies of Clinistix, and to the British Diabetic Association for financial and other support.

Beta-adrenergic Blockade and Cardiac Arrhythmias*

GRAEME SLOMAN,[†] M.B., B.Sc., M.R.C.P., M.R.C.P.E.D., M.R.A.C.P.; MARY STANNARD,^{‡‡} M.B., B.S.

Brit. med. J., 1967, 4, 508-512

The evaluation of beta-adrenergic blockade in cardiac arrhythmias is difficult because of the complex nature of the arrhythmias and the varied modes of action of blocking drugs. Studies have confirmed the therapeutic value of the beta-adrenergic blocking drug pronethalol (Alderlin) (Vaughan Williams, 1963; Stock and Dale, 1963; Payne and Senfield, 1964; Wolfson *et al.*, 1966) and its more potent successor, propranolol (Inderal) in the management of many different atrial and ventricular arrhythmias (Harrison *et al.*, 1965; Sloman *et al.*, 1965; Stock, 1966; Harris, 1966; Szekely *et al.*, 1966; Cherchi *et al.*, 1966; Rochet and Vastesaeger, 1966; Gettes and Surawicz, 1966; Luria *et al.*, 1966; Epstein and Braunwald, 1966).

This study reports our experience in the management of patients with paroxysmal arrhythmias, acute life-threatening arrhythmias, and recurrent arrhythmias associated with prolonged cardiac arrest. An attempt has also been made to assess the prophylactic value of propranolol in reducing the high incidence of arrhythmias associated with acute myocardial infarction.

Materials and Methods

Thirty-one patients presenting with various cardiac arrhythmias were included in this study. Patients in whom full documentation was not available were not included. There

* Presented at a National Heart Foundation of Australia Symposium held in Canberra, 25-27 January 1967.

^{‡‡} Research assistant supported by the National Heart Foundation of Australia Grant-in-aid G. 428.

were 19 males and 12 females, with an age range from 17 to 78 (mean 50.9 years). In all these patients the arrhythmia had proved disabling; in some it was associated with prolonged cardiac arrest.

Forty-nine patients with acute myocardial infarction were studied to assess the prophylactic value of propranolol in preventing arrhythmias. The patients were divided into four major groups: group A, chronic arrhythmias, recurrent and continuous; group B, acute arrhythmias; group C, arrhythmias associated with prolonged cardiac arrest; and group D, acute myocardial infarction.

Propranolol was given intravenously or orally, depending on the urgency of the clinical situation: the details of drug therapy are discussed under each group.

Results

Group A: Chronic Arrhythmias, Recurrent and Continuous

There were 16 patients in this group (Table I). Four had atrial fibrillation, not adequately controlled by digitalis or other anti-arrhythmic drugs. In three the fibrillation was paroxysmal, frequently causing syncope at its onset. In the fourth fibrillation was continuous, but the rate could not be adequately controlled by digitalis alone. There were five patients with paroxysmal atrial tachycardia, not adequately controlled by digoxin and quinidine sulphate. Four patients had other atrial arrhythmias, while the remaining three were in sinus rhythm with frequent ventricular ectopic beats, but suffered syncopal attacks due to paroxysmal ventricular tachycardia.

TABLE I.—*Propranolol. Chronic Arrhythmias, Recurrent and Continuous*

Case No.	Age	Sex	Presenting Symptoms	Arrhythmia	Failed Therapy	Propranolol Dose	Results
<i>Atrial Fibrillation</i>							
1	52	F	Syncope	Paroxysmal	Digitalis	40 mg. 4 × /day	No syncope

16	17	F	Palpitations. Syncope	Frequent V.E.S. with coupling on exercise	Quinidine	10 mg. 4 × /day	"

V.E.S. = Ventricular extrasystoles. D.C. = Direct current.

When the arrhythmia could be produced by exercise on the treadmill (Cases 1, 3, 7, 8, 11, 14, and 16) after recording the abnormal rhythm the patient was rested, given an intravenous dose of propranolol (0.1 mg./kg. body weight with 1.2 to 2.4 mg. of atropine sulphate), and after 10 minutes the exercise study was repeated (Fig. 1). Provided the arrhythmia was controlled propranolol was continued in an oral dose, beginning with 10 mg. every six hours. The dose was increased as necessary to a maximum in this study of 60 mg. four times a day.

FIG. 1.—Electrocardiograms at rest and during exercise, showing the effect of propranolol in preventing atrial fibrillation.

In the four patients with atrial fibrillation symptoms were controlled in three when propranolol was added to their regimen (Cases 1, 2, and 4). In Cases 1 and 2 the paroxysms continued, but syncope did not occur. In Case 3 syncopal attacks continued to occur with exercise despite full treatment with digitalis, quinidine, and pronethalol. Endocardial pacing was then begun; however, the rhythm still alternated between a sinus mechanism and atrial fibrillation. With digitalis and pacing alone syncope continued to occur, but when propranolol was added syncope did not occur.

In the patients with paroxysmal atrial tachycardia the arrhythmia was suppressed provided the dose of propranolol was maintained, except in Case 5, where digoxin was necessary as well as the propranolol. When one patient (Case 7) discontinued treatment after three years he experienced one severe attack before resuming therapy. Two of the four patients with other atrial arrhythmias were suffering from a cardiomyopathy (Cases 10 and 11). Despite a failed direct current reversion in Case 11, both patients reverted to a sinus mechanism while receiving propranolol in addition to other medication. The patient with persistent unexplained sinus tachycardia (Case 12)

showed a satisfactory reduction in rate, as did the patient with rapid atrial flutter due to thyrotoxicosis. The arrhythmia in this case reverted to sinus rhythm when the thyrotoxicosis was controlled. In the group with ventricular ectopic beats propranolol reduced the ectopic beats and prevented the syncopal attacks.

Group B: Acute Arrhythmias

The seven patients included in this group had serious arrhythmias of acute onset associated with severe cardiac disease (Table II), and the dose and route of administration of propranolol varied with the type of the arrhythmia and the urgency of the clinical situation. In two patients the arrhythmia was associated with acute myocardial infarction and in three others coronary artery disease was associated with pulmonary embolism, digitalis toxicity, and a past history of paroxysmal atrial tachycardia respectively. Of the remaining two, one developed multifocal ventricular extrasystoles while undergoing surgery for subarachnoid haemorrhage, while the other had rapid atrial fibrillation associated with an alcoholic cardiomyopathy.

There were two patients with acute myocardial infarction. In one atrial flutter occurred (Case 17). After propranolol the ventricular rate slowed initially, and later there was reversion to sinus rhythm. In the other (Case 21) paroxysmal ventricular tachycardia was rapidly suppressed with oral propranolol (Fig. 2). Of the three patients with coronary disease propranolol proved effective in controlling both atrial and ventricular arrhythmias. In Case 18 multiple atrial and ventricular arrhythmias were controlled after quinidine, digoxin, and phenytoin sodium (Dilantin) had proved unsuccessful. In Case 23 an episode of very rapid nodal tachycardia with cardiac

TABLE II.—*Propranolol. Acute Arrhythmia*

Case No.	Age	Sex	Aetiology	Arrhythmia	Failed Therapy	Propranolol Dose and Route	Result
17	65	M	Acute infarction	Atrial flutter	Digoxin	10 mg. 4 × /day orally	Initial recurrence, but later controlled
18	66	F	Coronary artery disease. Pulmonary embolism	Atrial flutter. Atrial tachycardia. Ventricular tachycardia	Phenytoin sodium. Quinidine. Digoxin	10 mg. 4 × /day orally plus digoxin	Control
19	40	M	Subarachnoid haemorrhage. Anaesthetic	Multiple ventricular extrasystoles	Nil	2.5 mg. I.M. plus atropine 1.2 mg.	"
20	78	M	Coronary artery disease. Digitalis toxicity	Atrial tachycardia. Atrial fibrillation	Lignocaine I.V.	5 mg. I.V. followed by 10 mg. 3 × /day for 3 days	"
21	57	M	Acute infarction	Runs of ventricular tachycardia	Quinidine	20 mg. statim orally. 10 mg. 6-hourly decreasing doses	Control. Propranolol continued 7 days
22	61	M	Alcoholic cardiomyopathy	Atrial fibrillation	Digoxin	5 mg. I.V.	Control initially, but treatment not continued, and patient died
23	65	F	Coronary artery disease	Nodal tachycardia	"	Pronethalol 60 mg. I.V.	Control

failure was suppressed when intravenous pronethalol was administered to the patient in whom the arrhythmia had not been controlled with full doses of digitalis (Fig. 3). In Case 20 digitalis toxicity was present and atropine premedication produced very rapid atrial tachycardia. This was slowed with 50 mg. of lignocaine intravenously, and reverted to sinus rhythm after propranolol 5 mg. intravenously. In Case 19

FIG. 3.—Selections from a continuous electrocardiogram taken during the administration of intravenous pronethalol.

the ventricular ectopics were rapidly controlled with intravenous propranolol. In Case 22, a patient with severe alcoholic cardiomyopathy, the ventricular rate was controlled, but the drug was inadvertently discontinued and subsequently the patient died.

Group C: Arrhythmias Associated with Prolonged Cardiac Arrest

There were eight patients in this group (Table III). In one propranolol was used initially, while in the remainder there had been prolonged cardiac arrest associated with resistant or recurrent ventricular fibrillation not responding to usual resuscitation methods, including the correction of acidosis, together with the administration of procainamide (Pronestyl) or lignocaine. In one (Case 25) 250 mg. of phenytoin sodium intravenously had also failed to maintain sinus rhythm.

In these patients the intravenous dose of propranolol ranged from 1 to 15 mg. The drug was always given cautiously in increments of 1 to 2 mg. covered by a single dose of atropine sulphate, 1.2 to 2.4 mg. intravenously. The duration of external

cardiac massage varied from 20 to 120 minutes before the administration of propranolol. In one patient (Case 24) propranolol alone was used to terminate ventricular tachycardia. In Case 25 ventricular fibrillation recurred after reversion with direct current counter shock on nine occasions (Fig. 4). Propranolol was administered after further counter shock and the patient then remained in sinus rhythm. In the other six patients (Cases 26 to 31) propranolol was given before direct current counter shock and in all cases satisfactory cardiac function was restored. All survived at least 12 hours, with four long-term survivors. Of the four deaths only one (Case 28) was due to a complication of drug therapy. This case has been

FIG. 4.—Selections from a continuous electrocardiogram taken during recurrent cardiac arrest: (a) supraventricular tachycardia; (b) ventricular fibrillation; (c) ventricular flutter; (d) ventricular fibrillation and the effect of direct current shock.

previously reported (Sloman *et al.*, 1965). Complete heart block developed while the patient was still receiving propranolol by slow intravenous infusion. The drug was not stopped, and the patient died in ventricular standstill.

Group D: Acute Myocardial Infarction

Forty-nine patients admitted to the coronary care ward with proved acute myocardial infarction were studied to assess the possible prophylactic value of propranolol in reducing the inci-

dence of arrhythmias associated with acute infarction. Those with cardiogenic shock, complete heart block, or a past history of asthma were excluded from the trial. Patients were allocated to the treatment or the control group by random numbering. Twenty-six patients received propranolol, initially by the intravenous route in a dose of 0.1 mg./kg. body weight with 1.2 mg. of atropine sulphate followed by oral propranolol 10 mg. every four hours, beginning one hour after the intravenous injection and continuing for up to three weeks. Atropine sulphate 0.6 mg. intramuscularly four-hourly was continued for 12 hours and then propantheline 15 mg. eight-hourly was substituted. The control group comprised 23 patients who received treatment with analgesics, anticoagulants, diuretics, and digitalis as indicated, but no anti-arrhythmic drugs. If a significant arrhythmia developed in either group it was treated on its merits, usually with procainamide 500 mg. intramuscularly, repeated four-to-six-hourly as necessary. The patients remained in the coronary care unit for a minimum of 72 hours with continuous electrocardiographic monitoring throughout their stay. Alterations in rate or rhythm and conduction were documented by a 10-second recording of the electrocardiogram every 30 minutes, together with recordings of any arrhythmia which activated the automatic recorder or which was observed by the nursing staff. All arrhythmias were counted and the treated and control groups compared (Table IV).

TABLE IV.—*Classification, Deaths, and Incidence of Serious Arrhythmias in Propranolol Trial*

	Propranolol	Control
Mild	16	15
Severe	10	8
Shock	0	0
Deaths	3	4
No. of patients with serious arrhythmias ..	3	5
.. „ episodes of serious arrhythmias ..	4	5

Apart from atrial, nodal, and ventricular ectopic beats, which were common and of similar incidence in both groups, the incidence of serious arrhythmias was slight. In the group receiving propranolol one patient had two episodes of ventricular fibrillation and another two short episodes of ventricular tachycardia. There were three deaths in the treated group, one due to cardiogenic shock, another to brain damage following resuscitation from ventricular fibrillation, and the third due to ventricular fibrillation which occurred after the patient was discharged from the coronary care unit.

The incidence of non-specific side-effects was nil. One patient developed cardiogenic shock and another Wenckebach heart block after the administration of propranolol, but hypotension and cardiac failure were neither severe nor frequent.

In the control group two patients had short episodes of ventricular tachycardia and another prolonged slow ventricular tachycardia, which required treatment with procainamide. One patient developed ventricular fibrillation while in the coronary care unit and died, while another developed ventricular fibrillation in a general ward and was successfully resuscitated. The remaining two deaths in this group occurred in the general ward after discharge from the coronary care unit, and the mode of death is unknown. There was therefore no indication that propranolol reduced the frequency of arrhythmias in patients with acute myocardial infarction, but to reach a valid statistical conclusion much larger numbers would have to be studied.

Discussion

These clinical observations indicate that beta-adrenergic drugs have an important place in the treatment of acute and chronic arrhythmias irrespective of their origin or cause. These results are in agreement with previously published reports.

Propranolol was found to be useful in controlling the rate of ventricular response in patients with paroxysmal atrial fibril-

lation and flutter. The drug was used with digoxin, and syncope and giddiness no longer occurred. Syncope was also prevented by propranolol and digoxin when combined with endocardial pacing, supporting the work of Harris (1966), who was able to reduce the number of ventricular ectopic beats occurring during cardiac pacing by the use of oral propranolol when large doses of quinidine and procainamide had not been successful.

The efficacy of propranolol in preventing paroxysmal arrhythmias may be reliably assessed by provoking the arrhythmia by exercise on a treadmill and repeating the exercise on a treadmill after the administration of intravenous propranolol.

There appears to be a special place for the use of propranolol in patients with prolonged cardiac arrest associated with resistant, recurrent ventricular fibrillation. Propranolol has been shown to have an anti-fibrillatory effect, and we believe it should be used when standard resuscitation methods and drugs have not produced a satisfactory cardiac rhythm. It was found that a satisfactory anti-arrhythmic effect could be produced with a dose of propranolol much smaller than a recognized beta-blocking dose, supporting the work of Stickney *et al.* (1966) and Howe and Shanks (1966), who showed that the drug has a biphasic mode of action. Propranolol should therefore be given in small intravenous doses of 1–2 mg., repeated as necessary, and covered by a full dose of atropine sulphate to prevent overactivity of the unmasked parasympathetic nervous system. As propranolol appears to have an anti-arrhythmic effect which is not due to its beta-blocking effect it would therefore seem reasonable in certain circumstances to use propranolol in combination with isoprenaline. We have used this combination with success in six patients. In Cases 27, 28, 29, and 31 both drugs were used during resuscitation, and in Cases 25 and 26 isoprenaline was used after successful resuscitation without producing further ventricular fibrillation.

In Case 28 complete heart block developed after successful resuscitation. A slow intravenous infusion was continued, whereas cessation of the drug, followed by the administration of isoprenaline and perhaps endocardial pacing, may have led to a successful outcome.

Trials of the prophylactic value of propranolol in acute myocardial infarction were given impetus by the work of Snow (1965), who reported a mortality of 13% in 52 patients treated with propranolol compared with 29% mortality in a comparable control group of 55 patients. However, in our study of a relatively small group of patients monitored after infarction we found no significant difference in the incidence of arrhythmias. Studies by Clausen (1966), Balcon *et al.* (1966), and Barber *et al.* (1966) have failed to confirm any difference in mortality in patients treated with oral propranolol or to demonstrate a difference in the incidence of arrhythmias. In addition, initial favourable results prompted the arrangement of a multicentre double-blind trial which was reported by Stephen (1966). Ten centres participated, providing data on 195 patients, and no difference in mortality between treated and untreated group was demonstrated. Pentecost (1966) has questioned the amount of absorption of propranolol given orally in the early stages after myocardial infarction, as this was the mode of administration in these trials. However, in our studies the initial dose was always given intravenously, but, even so, no difference in the incidence of arrhythmias was detected.

The whole question of prophylactic treatment of cardiac arrhythmias after acute infarction is now under intense study. We accept the hypothesis of Lown and Killip (personal communications, 1966) that certain arrhythmias, particularly ventricular extrasystoles when they occur frequently, arise from multiple ventricular foci or occur in runs, are forerunners of more serious potentially lethal arrhythmias, and must be treated at once. Procainamide, propranolol, phenytoin sodium,

and lignocaine may be used by the intravenous route to suppress these arrhythmias, but why one morphological type of ventricular ectopic will respond to one of the above anti-arrhythmic drugs and not to another remains to be studied. Currently, lignocaine is the drug of choice because of its high therapeutic effect compared with its relatively slight negative inotropic effect. It is used in incremental doses up to 200 mg.

Summary

Thirty-one patients with cardiac arrhythmias were treated with beta-adrenergic blocking drugs propranolol and pronethalol. Propranolol was found to be particularly useful in the management of rapid arrhythmias when other anti-arrhythmic drugs had not been successful. Beta-adrenergic blockade was of value in reducing the ventricular rate in paroxysmal atrial fibrillation, atrial flutter, and rapid atrial and sinus rhythms. Propranolol also possessed a specific anti-arrhythmic effect not clearly related to its beta-adrenergic blocking effect, and was found to be useful in the treatment of ventricular extrasystoles, paroxysmal ventricular tachycardia, ventricular arrhythmias associated with digitalis intoxication, and recurrent and resistant ventricular fibrillation.

Forty-nine (26 treated, 23 control) patients with acute myocardial infarction were studied to assess the prophylactic value of propranolol in reducing arrhythmias in acute myocardial infarction. The drug was administered intravenously initially in a dose of 0.1 mg./kg./body weight together with atropine sulphate 1.2 mg. followed by 10 mg. of propranolol orally four-hourly for three weeks. There was no difference in the incidence of arrhythmias between the two groups.

Our thanks are due to the medical staff, Royal Melbourne Hospital, who allowed us to treat patients under their care. The propranolol used in this study was made available by Dr. Charles Proctor (Medical Director, I.C.I., Australia), to whom we are grateful. Mr. J. R. Bainbridge, Computer Centre, Monash University, advised on the statistical treatment of the results from the coronary care ward.

Serum Folate Values in 423 Psychiatric Patients

M. W. P. CARNEY,* M.D., M.R.C.P.I., D.P.M.

Brit. med. J., 1967, 4, 512-516

With the widespread introduction of efficient ways of estimating serum folate, there have been reports of folate deficiency in malnutrition (Gough *et al.*, 1963), old age (Read *et al.*, 1965), a number of chronic physical illnesses (Batata *et al.*, 1967), neurological disease (Grant *et al.*, 1965), and patients receiving anticonvulsants, barbiturates (Klipstein, 1964; Malpas, 1966), antibiotics, and cytotoxic agents (Dr. E. J. Watson-Williams, personal communication). Folate deficiency and psychiatric conditions have also been associated—for example, anxiety/depression (Gough *et al.*, 1963) and dementia (Henderson *et al.*, 1966)—while 12 out of 43 patients with subnormal serum folate were currently attending a psychiatric department (Forshaw, 1965). Reynolds (1966, 1967) has gone so far as to suggest a causal relation between folate deficiency and certain forms of mental illness, especially affective changes and, in long-standing cases, dementia. There seems, however, to have been little systematic investigation of the incidence of folate deficiency in psychiatric populations.

These reports encouraged me to ascertain the incidence of low serum folate levels in a psychiatric population and its relation to a number of variables, including diagnosis, age, nutrition, physical state, drugs, and chronicity of illness. Though this investigation was not specifically designed to answer the question, it was felt that some clues regarding the

possible aetiological significance of folate deficiency in mental illness might appear.

Method and Material

Serum folate estimations were carried out on consecutive admissions to two psychiatric units 20 miles (32 km.) apart, one a general hospital unit and the other a mental hospital. They were all under my personal care and were admitted over a period slightly exceeding a year. Though the hospitals served the same geographical area they dealt with somewhat different psychiatric populations, the mental hospital tending to admit the more disturbed and more chronic patients. The intakes of both units were studied concurrently in order to ensure that the whole group was representative with respect to diagnosis, age, and sex of those psychiatric patients within the catchment area for whom admission to hospital was judged to be needed. Within individual subcategories of patients there was little variation in folate levels between the two hospitals.

Serum folate estimations were carried out by an adaptation of the method of Waters and Mollin (1961) by which folate activity was measured by reading turbidimetrically the growth of *Lactobacillus casei* A.T.C.C. 7469 after incubation in the sample solution for 48 hours at 37° C.: the results were calculated from a standard graph. These estimations were carried out in two different laboratories, but the procedures in both were identical.

* Consultant Psychiatrist, Blackpool and Fylde Hospital Group and Lancaster Moor Hospital.

Serum folate estimations were also carried out on nursing, medical, and clerical staff, mental welfare officers, and ambulance drivers—all volunteers. These constituted a control series; so far as was known none of them was receiving psychiatric treatment and all appeared to be physically fit.

There were 423 patients of mean age 54.04 ± 9.61 (282 females and 141 males). There were 62 controls of mean age 39.2 ± 12.65 (31 females and 31 males). Patients and controls differed significantly as regards age and sex, but since these factors were not found to be significantly associated with the folate levels within the context of the present investigation, they are probably of little importance. Only one patient had been receiving Cytamen (cyanocobalamin) previous to admission, none had received folic acid, and none was diagnosed as suffering from subacute combined degeneration of the cord.

Because of the undoubted influence of certain drugs in lowering the serum folate, blood was obtained as soon as possible after admission and nearly always before treatment was begun. Simultaneously, samples were sent to the laboratory for vitamin B₁₂ estimations. This paper does not deal with the breakdown of the B₁₂ results except where they seem to be relevant to the folate findings.

Results

The mean serum folate for the patients was 3.2 ± 1.73 $\mu\text{g./ml.}$ and for the controls 3.6 ± 1.5 $\mu\text{g./ml.}$ This difference is not quite significant ($t=1.92$; $P>0.05$). However, Fig. 1 shows a distinct clustering of the patients at the lower end of the scale not matched by the controls. If a folate level of 2 $\mu\text{g./ml.}$ is taken as the dividing point, there are only six controls as against 105 patients below this point. This difference is significant at the 1% level ($\chi^2=6.89$; $\text{d.f.}=1$). Values of serum folate below 2 $\mu\text{g./ml.}$ are hereafter referred to as "low folate."

FIG. 1.—Serum folate levels: psychiatric patients compared with normal controls.

Age.—Depressed folate levels have often been found in geriatric patients. The relation between various age groups and their mean folate values is shown in Table I. There is obviously

TABLE I.—Mean Serum Folate Levels for Various Age Groups

	Age in Years							Overall Mean
	10-29	30-	40-	50-	60-	70-	80+	
Mean serum folate (μg./ml.)	3.2	3.6	3.1	3.4	3.0	3.0	3.1	3.2

no constant relation here. The mean ages of the low (53.8 ± 17.6) and normal folate (54.3 ± 17.12) patients did not differ significantly.

Sex.—The sex distribution did not alter with the serum folate level.

Haematological Findings.—A full blood count was made and a blood film taken in all patients. Of those with low folate values, 28 had haemoglobins of less than 80% and five had other abnormalities such as anisocytosis. Thus 33 (31.4%) of these patients had a haematological abnormality; of these seven showed macrocytosis and three had a low serum B₁₂. On the other hand, only 33 (10.7%) of patients with normal folate results had a haemoglobin below 80% or showed abnormality, and none had macrocytosis. The difference between the two groups is significant ($\chi^2=24.94$; $\text{d.f.}=1$; $P<0.001$).

Sternal Marrow.—A very small number of patients with evidence of anaemia, etc., were given sternal marrow puncture and a specimen of marrow was examined. Only one of these was unequivocally megaloblastic and this patient, besides having a serum folate of 1.2 $\mu\text{g./ml.}$, also had a serum B₁₂ of less than 25 $\mu\text{g./ml.}$ Thus in the present study no certain evidence of megaloblastic marrow change was found to be associated with a low folate value. This does not mean that megaloblastic marrow would not have been found if more sternal punctures had been performed. Obviously there is a limit to the frequency of this uncomfortable and sometimes frightening procedure in the psychiatric setting. Moreover, many of these patients were not very co-operative.

Folate Deficiency and Serum Vitamin B₁₂.—There have been reports that folate deficiency has resulted in subnormal serum B₁₂ levels with a return to normal after administration of folic acid (Forshaw *et al.*, 1964). In 368 of the present patients the serum B₁₂ result was available and there seems to be an association between the lower values of serum folate and a serum B₁₂ level below 150 $\mu\text{g./ml.}$ (hereafter called "low" B₁₂) (Table II). Patients with serum folate less than 2.9 $\mu\text{g./ml.}$ are significantly more liable to low serum B₁₂ than otherwise ($\chi^2=4.15$; $\text{d.f.}=1$; $P<0.05$). This finding, apart from its theoretical interest, is of practical importance. It has long been recognized that folic acid therapy in the presence of clinically occult vitamin B₁₂ deficiency can precipitate subacute combined degeneration. It seems prudent, therefore, to assess the vitamin B₁₂ status of folate-deficient patients before embarking on folic acid therapy.

TABLE II.—Incidence of Low Serum Vitamin B₁₂ (<150 $\mu\text{g./ml.}$) for Various Levels of Serum Folate

Serum folate (μg./ml.)	0-1.5 (n=56)	1.6-1.9 (n=46)	1.9-2.9 (n=100)	>2.9 (n=166)
Patients with low B ₁₂ (%)	21.4	15.2	15	10.2

Psychiatric Diagnosis

Table III shows the patients classified into diagnostic groups with mean ages, ranked in order of magnitude of mean serum folate. There is no corresponding progression of age, confirming that there is no clear-cut relation between serum folate and age. The following diagnostic groups have significantly lower

TABLE III.—Diagnostic Groups: Mean Ages and Mean Folate Levels Compared with Mean Folate Level for Controls (3.6 ± 1.5 $\mu\text{g./ml.}$)

Diagnosis	No.	Age (years)	Serum folate (μg./ml.)	Significance	
				t	P
Chronic alcoholism	27	46.4	6.3 ± 3.0	4.6	<0.001
Mania	18	54.0	4.1 ± 2.0		N.S.
Drug addiction	12	47.5	3.5 ± 1.6		N.S.
Schizophrenia	78	41.8	3.4 ± 1.6		N.S.
Neurosis (neurotic depression excepted)	30	48.9	3.3 ± 1.6		N.S.
Neurotic/reactive depression	71	47.7	3.2 ± 1.7		N.S.
Abnormal personality	15	34.5	3.2 ± 1.2		N.S.
Endogenous depression	75	55.0	3.0 ± 1.7	2.3	<0.05
Organic psychoses	90	72.9	2.9 ± 1.5	2.7	<0.01
Epilepsy	7	47.5	1.7 ± 0.8	7.2	<0.001
Total	423	54.04 ± 9.61	3.2 ± 1.73		

N.S. = Not significant.

mean serum folate values than the controls: epilepsy, organic psychoses, and endogenous depression; the only diagnosis with a mean serum folate significantly above that of the controls is chronic alcoholism.

In elucidating the relation between folate deficiency and psychiatric diagnosis, it was decided to exclude those patients with a low serum vitamin B₁₂, as this condition is thought to cause mental illness, and it has just been shown that this could have influenced the clinical picture in patients with the lower serum folate levels. Fig. 2 shows the distribution of patients with low serum folate values and normal serum vitamin B₁₂ among the various diagnostic groups ("organic" comprises dementia and delirious/subdelirious states; "others" include neurosis, abnormal personality, mania, drug addiction, and chronic alcoholism). Not unexpectedly, epilepsy has the highest proportion, with, surprisingly, depression next and organic psychoses coming only third. The distribution of diagnoses among the low folate patients is significantly different from that of patients with normal folate ($\chi^2=13.55$; d.f.=4; $P<0.01$). This situation is quite different from the distribution of diagnoses among patients with low serum B₁₂ levels, where organic states have a clear lead (Fig. 3).

Fig. 2.—Low serum folate levels and psychiatric diagnosis in 317 patients.

Fig. 3.—Low serum vitamin B₁₂ and psychiatric diagnosis in 377 patients.

The 19 patients with both low serum folate and vitamin B₁₂ levels tended to conform to the diagnostic pattern of the low serum B₁₂ group; thus there were eight organics, four endogenous depressives, three schizophrenics, two neurotic depressives, one other neurotic, and one chronic alcoholic.

Further Study of Low Serum Folate Group

The patients with low serum folate levels were more intensively studied for other aetiological factors, both by clinical examination and investigation and by social history-taking from relatives, etc., and consultation with the general practitioners. These last were particularly helpful in ascertaining the patients' preadmission medication (if any). The following results all refer to this group:

(a) *Drugs*.—Of the 105 patients, 79 (75%) had been on drugs in the three weeks before admission. The breakdown of these is presented in Table IV. The figures do not add up, because some patients had more than one drug. They are divided into drugs widely recognized as depressing serum folate and other drugs. Not unexpectedly barbiturates and anticonvulsants predominate among the former and phenothiazines and antidepressants among the latter. Of course any group of psychiatric patients might be expected to show this kind of drug pattern. The appropriate way of demon-

strating an association between low serum folate and drugs would be by comparing the preadmission drug intakes of low and normal folate groups. Unfortunately it was not possible to obtain this information for the normal serum folate group, but it was collected for those patients with low serum B₁₂. The preadmission drug patterns for both groups are compared in Table V, patients with simultaneous depression of serum folate and B₁₂ having been excluded. It is clear that the low folate group have had drugs far more frequently than the low serum B₁₂ patients, suggesting that psychotropic drugs are, in some way as yet unclear, associated with low serum folate levels. Of course the variation could be accounted for by other differences between the two groups.

TABLE IV.—*Drugs* and Serum Folate <2 µg./ml.*

Drugs cited as depressing serum folate:	No. of patients
Barbiturates	29
Anticonvulsants	5
Phenylbutazone	2
Antibiotics	1
Other drugs:	
Phenothiazines	22
Tricyclic antidepressants	9
Chlordiazepoxide	7
M.A.O. inhibitors	4
Others	8

* Some patients had more than one drug.

	No. of Cases	Drugs	No Drugs
Serum folate <2 µg./ml. and normal serum B ₁₂	86	68	18
Serum B ₁₂ <150 µg./ml. and normal serum folate	34	15	19
Total	120	83	37

$\chi^2=13.89$; d.f.=1; $P<0.001$.

(b) *Gastrectomy and Pregnancy*.—Only four of these patients had had a gastrectomy and only three were pregnant; thus these factors appeared to be relatively unimportant in the present context.

(c) *Gross Malnutrition*.—Twenty-four, or 22.9% of the group, including two food cranks and six patients with nutritional oedema, were suffering from this condition. No patient with intestinal malabsorption was found.

(d) *Physical Illness*.—An increasing number of chronic physical illnesses are being associated with folate deficiency. Might not much of the present serum folate subnormality be due to concomitant physical illness apart from gross malnutrition? Eighteen, or 17%, of the patients were physically ill: 10 with cardiovascular disease, four with chronic bronchitis, two with Parkinsonism, and one each with myxoedema and pulmonary tuberculosis. There were no examples of myeloclerosis or rheumatoid arthritis.

Thus there is little support for the idea that chronic physical illness, malabsorption, and malnutrition are solely responsible for folate deficiency. On the other hand, of 105 patients with a low serum folate, as presently defined, only 21 patients were free of a recent drug history, poor nutritional status, gastrectomy, pregnancy, and chronic physical illness. A further five had a low serum B₁₂ level, so that only 16 patients were without any recognized or suspected cause of folate deficiency. These 16 patients constitute the "idiopathic" low folate group, and one would expect these patients to show in pure culture the link, if any, between the avitaminosis and the sort of mental disturbance associated with it. However, the patients came from a broad psychiatric spectrum covering schizophrenia, dementia, chronic alcoholism, endogenous and neurotic depression, neurosis, and psychopathy. Thus the "primary" or "idiopathic" deficiency was not obviously associated with any particular mode of psychiatric presentation.

(e) *Chronicity of Mental Illness*.—In assessing chronicity very frequent episodes of illness with only brief periods of remission between, say, a week or two were counted as one period of continuous illness. The following figures relate to the interval between onset of present illness and present hospitalization: ill for less than three months, 13.4% of patients; three months to one year, 21.2%; one to three years, 21.2%; over three years, 44.2%. The proportion of chronic cases is almost certainly much higher than for the generality of hospitalized psychiatric patients. These findings raised the interesting speculation of which came first, the chronicity

or the folate deficiency? The long-term results of a trial of folic acid in the chronically mentally ill with a low serum folate might help to clear up the point.

There is evidence to suggest (Batata *et al.*, 1967) that subnormal serum folate is a nonspecific result of illness in general. It could therefore be expected that low values would occur with greater frequency with increasing duration of illness, irrespective of diagnosis; thus the syndromes with the highest proportion of depressed levels would be those with the greatest excess of chronic cases. The above findings to some extent support this idea, but can any importance be allotted to diagnosis? If chronicity were decisive the patients with low serum folate could be expected to be uniformly chronic within each diagnostic subgroup. In fact, this was found to be not so. The individual diagnoses vary widely for proportions of chronic cases; thus 66% of the subnormal folate schizophrenics had been ill for more than three years compared with 28% of the endogenous depressives. The figures for neurotics and organics were 50% and 36% respectively. This finding suggests that diagnosis has an association with low serum folate independent of duration of illness.

Discussion

This study was not designed to be a comprehensive investigation of the aetiology and biochemistry of folate deficiency: it was intended to be a preliminary screening of a representative sample of major mental illness in a defined community of population 300,000—namely, Blackpool and the Fylde. Nevertheless, within these limits some aetiological pointers emerged and certain tentative inferences can be drawn. The most striking result was the frequency of subnormal serum folate at 22.5% of the patients surveyed. However, the assumption that a low serum level of folate *invariably* indicates a folate deficiency state is not justified. Falsely low levels can occur as the result of the in-vivo and in-vitro actions of certain drugs—a possibility supported by the present findings; phenothiazines can suppress test organisms in biological assay—for example, the influence of chlorpromazine on *E. gracilis* (Herbert *et al.*, 1965)—and other laboratory artifacts can arise. In this investigation a normal control series was used to exclude some of these pitfalls. Empirically, a serum folate of 2 $\mu\text{g./ml.}$ was found to be a useful lower limit of normality, though this figure is much lower than commonly accepted levels—a finding suggesting that these levels are perhaps pitched too high.

Nevertheless, it is likely that these low serum folate values reflect a physiological imbalance, common in certain forms of mental illness, which has usually not progressed to megaloblastic anaemia. However, it does not automatically follow that the imbalance plays a causal part in psychiatric illness (see below).

The most striking associations with low serum folate were chronicity of illness, a history of medication, usually barbiturates, phenothiazines, or antidepressants, and the predominance of certain diagnoses—namely, epilepsy, endogenous depression, and organic brain syndromes. Also frequently present were malnutrition and, to a less extent, chronic physical illness. Apparently the duration of illness alone was not responsible for the associations with diagnosis.

Can drugs have played the decisive part in depressing the serum folate? The vast majority of these patients had had drugs, especially those recognized as serum-folate-depressant-like barbiturates; phenothiazines were also so prominent as to suggest they have a similar action. However, drugs, like chronicity, cannot be the whole explanation for the results, because schizophrenics and neurotics, the most chronic and probably the most medicated patients, relatively seldom had a low serum folate. On the other hand, endogenous depression and organic states, despite being of shorter duration and less likely to provoke prolonged courses of drugs, were unequivocally low in mean serum folate values. If duration of illness and drugs did not play a decisive part, what did?

It was found that malnutrition and chronic physical debility, though not invariably associated with low serum folate, were evenly distributed among the low folate patients, irrespective of psychiatric diagnosis, with the exception of organic states which, not surprisingly, had a slight excess. The most widely accepted explanation for dietary deficiencies in psychiatric patients is apathy and self-neglect, secondary to the mental state. This is probably an oversimplified view. As Reynolds (1967) points out, mental illness, self-neglect, dietary deficiency, and further mental deterioration caused by the deficiency are linked in a vicious circle. But what caused the psychiatric condition in the first place? An alternative explanation is that, in the same patient, vitamin deficiencies including folate can both cause and be caused by a psychiatric illness. The problem of investigating the interactions of these factors is thus a complex one, and prospective studies as well as long-term therapeutic trials of folic acid in patients with deficiency states are needed.

Epileptics are widely recognized as liable to folate deficiency largely due to the effects of anticonvulsant drugs (Malpas *et al.*, 1966), but here again chronicity of illness and physical deterioration certainly contribute.

An interesting finding was the difference in the diagnostic patterns among the low serum folate and low serum B_{12} patients. There is widespread agreement (Shulman, 1967) that organic psychosis is typical of vitamin B_{12} deficiency, the psychiatric counterpart of subacute combined degeneration of the cord. The present findings with regard to the low serum B_{12} patients are in accord with this observation: surprisingly, the diagnostic associations of subnormal serum folate are radically different, especially with respect to depressive states. It can fairly be deduced that this association with functional rather than organic psychosis implies a difference in the underlying pathophysiological mechanism from that of vitamin B_{12} deficiency.

Can the present investigation throw any light on the aetiological role of folate in mental illness? Despite our inability to establish a simple one-to-one relationship between "uncomplicated" low serum folate and a particular psychosyndrome, the present observations agree with Reynolds's (1967) suggestion that affective disturbances and organic psychoses are the typical psychiatric manifestations of folate deficiency, with a precision which is unlikely to be coincidental.

An unexpected finding was the significantly raised mean serum folate of the chronic alcoholics. That this may be more than a mere clinical curiosity is indicated by a report by Magnus (1966) describing a case of jejunal blind-loop syndrome, peripheral neuropathy, and high serum folate. He suggested that the raised serum folate might have caused the peripheral neuropathy even in the presence of normal serum B_{12} . The relevance of this observation for chronic alcoholism, a condition in which peripheral neuropathy is common, is obvious.

Conclusion

What are the practical implications of these results? There are three: firstly, folate deficiency would appear to be common enough in the mentally ill to justify carrying out serum folate and B_{12} estimations as routine admission procedures; secondly, it would be wise to treat patients with subnormal serum folate values with folic acid supplements, and, if indicated, cyanocobalamin, in the hope of securing mental as well as physical improvement; and thirdly, further exploratory studies as already suggested should be carried out.

Summary

Serum folate estimations were carried out on 423 psychiatric inpatients, consecutive admissions to a general hospital and a

mental hospital unit, and 62 normal controls. Serum vitamin B₁₂ estimations were also done on 368 of the patients. Though patients and controls did not differ on mean serum folate, there were significantly more patients with values below 2 $\mu\text{g./ml.}$ ("low folate") than controls. Patients with epilepsy, organic psychoses, and endogenous depression had significantly lower mean serum folate, and chronic alcoholics significantly higher mean serum folate, than the controls; the former conditions also predominated among patients with low folate, a diagnostic pattern significantly at variance from that of patients with normal folate values and those with serum B₁₂ <150 $\mu\text{g./ml.}$ Low folate patients had more haematological abnormalities, including low serum B₁₂, than other patients; 75.2% had received drugs during the three weeks before admission, 22.9% showed evidence of malnutrition, 17% were physically ill, and 44.2% had been continuously ill for more than three years.

I wish to thank Drs. F. Yates, P. Harvey, and F. Hayes, Messrs. Orrell, Curd, Singleton, and Kilgariff, and Sisters Hetherington

and Morton for advice and co-operation; and Mrs. J. Taylor and Mrs. E. Jackson for clerical assistance.

Ascorbic Acid Nutrition in Gastroduodenal Disorders

MAX M. COHEN,* M.B., CH.B.; ANNE M. DUNCAN,† B.SC.

Brit. med. j., 1967, 4, 516–518

Frank clinical scurvy is a rare disease, but subclinical deficiency of ascorbic acid, as defined by low dietary intake of ascorbic acid and low blood levels, is common. Thus the significance of "subvitaminosis C" has been the subject of controversy since it was first described by Hess (1917). However, it is probably now accepted that, while under normal circumstances a low intake of ascorbic acid is harmless (Dahlberg, Engel, and Rydin, 1944), at times of stress, when there is increased utilization of ascorbic acid by the tissues generally (Faulkner and Taylor, 1937) and especially by wounded tissues (Crandon, Landau, Mikal, Balmanno, Jefferson, and Mahoney, 1958), dietary deficiency may render the patient vulnerable to infection (Heise and Martin, 1936) and the low blood ascorbic acid level may make the surgical patient more liable to wound dehiscence (Crandon, Lennihan, Mikal, and Reif, 1961).

Attention has recently been drawn to the low levels of leucocyte ascorbic acid seen in large numbers of surgical patients (Crandon *et al.*, 1961), in elderly patients (Bowers and Kubik, 1965), and particularly in patients with peptic disorders (Cohen, 1967).

The fundamental importance of vitamin C in the healing process has been demonstrated in guinea-pigs (Bourne, 1944; Penney and Balfour, 1949; Gould, 1958; Ellis, Harrison, and Hugh, 1965) and in humans (Hunt, 1941; Boyd and Campbell, 1950), the two animal species known not to synthesize ascorbic acid. It is therefore important to understand the significance of the low blood levels of ascorbic acid consistently found in patients with peptic ulcer (Harris, Abbas, Yudkin, and Kelly, 1936; Platt, 1936; Archer and Graham, 1936; Lazarus, 1937; Portnoy and Wilkinson, 1938), as in these patients surgery is often the treatment of choice.

In this investigation we have attempted to assess the extent of ascorbic acid deficiency in surgical patients, and in particular in those with duodenal ulcer, using the leucocyte ascorbic acid level, as this is now accepted as the best available index of ascorbic acid nutrition (Bartley, Krebs, and O'Brien, 1953), and to relate these findings to dietary intake of ascorbic acid.

Method

Leucocyte ascorbic acid levels were estimated by the method of Denson and Bowers (1961). Particular care was taken to avoid delays of more than several minutes between venepuncture and beginning the initial fractionation of the blood, as white blood cells take up ascorbic acid from the plasma on standing. Simultaneous estimations were made of the white blood cell count and platelet count to allow any necessary conversion factor to be applied (Gibson, Moore, and Goldberg, 1966); but in fact all of these counts fell within the accepted normal range and thus no conversion factor was necessary. The levels of ascorbic acid quoted subsequently represent the total ascorbic acid present in the white cells plus the platelets, though conventionally expressed as microgrammes per hundred million white blood cells ($\mu\text{g./10}^8$ W.B.C.).

The leucocyte ascorbic acid levels were estimated in 14 normal healthy young adults, all of whom were known to have an intake of ascorbic acid of at least 30 mg./day, the level of intake recommended by the Medical Research Council (Bartley *et al.*, 1953) and adopted by the British Medical Association.

A random sample of 50 patients admitted to a general surgical unit in a large city teaching hospital was investigated. All were admitted during November or December, a time of year when the autumn peak of ascorbic acid nutrition (National Food Survey Committee, 1966) would still be reflected in the leucocyte ascorbic acid level and above average levels could reasonably be expected. Dietary histories were obtained from all patients and normal subjects by one of us (M.M.C.) using a questionnaire based on the tables of McCance and Widdowson (1960).

Of the 50 patients investigated 14 were found to be suffering from some gastroduodenal disorder, and in all 14 the diagnosis was confirmed at laparotomy. Fourteen surgical patients with no known alimentary disease, matched for age and sex, were used as controls.

Nine of the 14 patients with gastroduodenal disorders had duodenal ulcer alone; all were treated surgically by total vagotomy and pyloroplasty. Eight of them were reviewed five months after surgery (one patient being lost to follow-up).

* Department of Surgery, Glasgow Royal Infirmary. Present appointment: Surgical Registrar, Western Infirmary, Glasgow W.I.

† Department of Biochemistry, Glasgow Royal Infirmary, Glasgow C4.

Results

(1) *Normals*.—In 14 normal young adults (eight male, six female) with a mean age of 22 years (S.D. ± 1.7) and on an adequate diet, the mean leucocyte ascorbic acid level was $21.7 \mu\text{g./}10^8 \text{ W.B.C.}$ (S.D. ± 4.6). The range of values was 15.0–29.0 $\mu\text{g./}10^8 \text{ W.B.C.}$ The mean dietary intake of ascorbic acid was 48 mg./day (S.D. ± 19.5), the range of values being 30–101 mg./day. In these subjects there was no correlation demonstrable between the level of intake of ascorbic acid and the leucocyte ascorbic acid level (Fig. 1).

(2) *Control Patients*.—In 14 control patients (seven male, seven female) with a mean age of 50 years (S.D. ± 17.0) and with no known alimentary disease the mean leucocyte ascorbic acid level was $22.9 \mu\text{g./}10^8 \text{ W.B.C.}$ (S.D. ± 5.9). The mean dietary intake of ascorbic acid in this group was 39 mg./day (S.D. ± 17.3). A strong correlation was observed between the ascorbic acid intake and the leucocyte ascorbic acid level (Fig. 2).

(3) *Gastroduodenal Disorders*.—The mean leucocyte ascorbic acid level in 14 patients (seven male, seven female) with gastro-duodenal disorders (mean age 50 years, S.D. ± 17.0) was $11.0 \mu\text{g./}10^8 \text{ W.B.C.}$ (S.D. ± 4.4). The mean dietary intake of ascorbic acid was 27 mg./day (S.D. ± 12.5). In this group there was fair correlation between the leucocyte ascorbic acid level and the dietary intake of ascorbic acid (Fig. 3).

(4) *Duodenal Ulcer Before Surgery*.—The mean leucocyte ascorbic acid level in the eight patients (five male, three female) with duodenal ulcer who were subsequently reviewed was $8.7 \mu\text{g./}10^8 \text{ W.B.C.}$ (S.D. ± 1.3). The mean dietary intake of ascorbic acid was 27 mg./day (S.D. ± 10.7), no correlation being demonstrable between this and the leucocyte ascorbic acid level (Fig. 4).

(5) *Duodenal Ulcer After Surgery*.—Five months after surgery, when the eight patients (five male, three female) with duodenal ulcer were reviewed, the mean leucocyte ascorbic acid level was found to be $12.8 \mu\text{g./}10^8 \text{ W.B.C.}$ (S.D. ± 4.3) and the mean dietary intake of ascorbic acid was 53 mg./day (S.D. ± 27.9). The relation between ascorbic acid intake and leucocyte ascorbic acid is shown in Fig. 4.

The results demonstrate no significant difference between the leucocyte ascorbic acid levels or ascorbic acid intakes of normal subjects and control patients. The dietary intake of ascorbic acid was significantly lower in patients with gastroduodenal disorders than in control patients ($P > 0.05$). No difference was demonstrated between the ascorbic acid intake of patients with duodenal ulcer and those with gastroduodenal disorders in general. The leucocyte ascorbic acid levels in patients with gastroduodenal disorders, and particularly duodenal ulcer, were significantly lower than in controls ($P > 0.01$).

While patients with duodenal ulcer had lower leucocyte ascorbic acid levels than patients with gastroduodenal disorders in general, this was not significant. After surgery for duodenal

ulcer, however, there was a significant rise in the leucocyte ascorbic acid level ($P > 0.05$) and in the dietary intake of ascorbic acid ($P > 0.01$).

In no patient was there any obvious clinical evidence of scurvy. None of the patients had clinical evidence of steatorrhoea or malabsorption, and in no patient was there any gross upset of haemoglobin level or of the plasma proteins. The patients who were reviewed after surgery for duodenal ulcer were well, offered no dyspeptic symptoms on specific questioning, and in particular none had post-vagotomy diarrhoea.

Discussion

The leucocyte ascorbic acid level has been shown to be significantly lower in patients with gastroduodenal disorders, and, in particular, in duodenal ulcer than in a control group. These patients have also been shown to subsist on a dietary intake of ascorbic acid below the 30 mg./day recommended by the British Medical Association (1950) at a time of year when dietary ascorbic acid could normally be expected to be above average. None of the patients subsisted on a "scurbutogenic" diet of less than 10 mg./day (Bartley *et al.*, 1953).

In patients with gastroduodenal disorders and in controls a correlation has been shown to exist between the dietary intake of ascorbic acid and the leucocyte ascorbic acid level. There was, however, no such correlation demonstrable in normal young adults on high intakes of ascorbic acid nor in patients with duodenal ulcer after surgery.

Low leucocyte ascorbic acid levels have been found in elderly patients (Bowers and Kubik, 1965), and this has been attributed to a reduced dietary intake of ascorbic acid (Andrews and Brook, 1966). Williamson, Goldberg, and Moore (1967) have found low leucocyte ascorbic acid levels in patients with malabsorption and after various gastric operations, in association with a normal intake of ascorbic acid, and they postulate the possibility of this being due to increased utilization of ascorbic acid in these circumstances.

Our findings suggest that the low leucocyte ascorbic acid level found in the patients with gastroduodenal disorder is due to dietary deficiency of ascorbic acid rather than to any increased utilization or malabsorption of ascorbic acid. This correlates well with everyday experience of the dietary habits of patients with dyspepsia.

Experiments in guinea-pigs have shown that ascorbic acid is essential for the formation of mature collagen in wounds (Robertson and Schwartz, 1953; Gould, 1958), and, in addition, that there is a definite correlation between the dietary intake of ascorbic acid and the rate of collagen formation (Robertson, 1961). It has also been shown that a dose of less than 5 mg. of ascorbic acid per day (5 mg. daily is roughly five times the amount necessary to protect the guinea-pig from

FIG. 4.—Relation of ascorbic acid intake to leucocyte ascorbic acid in eight patients with duodenal ulcer.

scurvy) is not adequate to permit a maximal collagen concentration in guinea-pig experimental carrageenin granulomas (Robertson, 1966).

Because of the technical difficulty of studying human wound healing it is not yet known whether there is a critical level of ascorbic acid nutrition below which wound healing is impaired. But the evidence from guinea-pig experiments, together with the evidence of a high incidence of poor ascorbic acid nutrition in patients suffering the complication of complete wound dehiscence (Crandon *et al.*, 1958), must make us view with concern the low leucocyte ascorbic acid levels we have shown in patients with gastroduodenal disorders.

Until it is shown conclusively that patients with low leucocyte ascorbic acid levels are at no greater risk of impaired wound healing it would appear mandatory that all patients who could be expected to have such low levels be given routine ascorbic acid supplements before surgery and during the phase of early wound healing. This can be done easily and very cheaply by means of oral ascorbic acid tablets, and in emergencies saturation can be achieved by the intravenous route. There are no known hazards of ascorbic acid therapy, and overdosage is therefore of no practical importance.

We have shown that after successful surgery for duodenal ulcer there was the expected return to a normal diet with an adequate intake of ascorbic acid. It is very interesting, however, that though the leucocyte ascorbic acid levels significantly improved after surgery they did not return to normal levels even after five months had elapsed. The turnover half-life of labelled ascorbic acid is approximately 20 days (Baker, Saari, and Tolbert, 1966), so no improvement in ascorbic acid nutrition could be expected with the further passage of time. A possible explanation of this finding is that after vagotomy and pyloroplasty there is a relative malabsorption of ascorbic acid. The absorption of ascorbic acid is impaired by achlorhydria (Alt, Chinn, and Farmer, 1939), so it may be that the therapeutic hypochlorhydria achieved by complete vagotomy is responsible for the failure of a normal diet to correct completely the abnormal leucocyte ascorbic acid levels found in patients with duodenal ulcer.

Summary

Fourteen patients with gastroduodenal disorders had significantly lower levels of leucocyte ascorbic acid than 14 control patients and 14 healthy young adults. The mean leucocyte ascorbic acid level in the test patients was $11.0 \mu\text{g./}10^8 \text{ W.B.C.}$ and in the control patients was $22.9 \mu\text{g./}10^8 \text{ W.B.C.}$ ($P > 0.01$).

Eight patients with proved duodenal ulcer had a reduced dietary intake of ascorbic acid and a low level of leucocyte ascorbic acid (mean $8.7 \mu\text{g./}10^8 \text{ W.B.C.}$). After vagotomy and pyloroplasty the dietary intake returned to normal and the

leucocyte ascorbic acid level increased significantly ($P > 0.05$) though normal levels were not achieved.

The significance of these findings was discussed, and it was recommended that patients with peptic ulcer should have routine supplements of ascorbic acid before surgery is performed and during the period of postoperative convalescence.

We are indebted to Mr. John Hutchison for his encouragement and permission to study patients in his wards, and to Professor H. G. Morgan and Sir David Cuthbertson for helpful advice and criticism. We are grateful to Dr. G. MacDonald for haematological estimations and to Miss Catherine M. Smith for assistance with the dietary investigations.

Clinical Experience with Bethanidine in Treatment of Hypertension*

JULIAN BATH, M.B., B.Sc., M.R.C.P.ED.; DOUGLAS PICKERING, M.B., M.R.C.P.ED.

RICHARD TURNER, M.D., F.R.C.P., F.R.C.P.ED.

Brit. med. J., 1967, 4, 519-521

At the present time probably most patients with high blood pressure in this country are being treated with guanethidine or methyl dopa with or without the addition of an oral diuretic. Because of certain disadvantages of these two drugs in our experience (Lowther and Turner, 1963; Johnson *et al.*, 1966) we have largely confined our attention during the past three years to debrisoquine (Kitchin and Turner, 1966) and bethanidine. Experience with the latter drug is the subject of this paper.

Pharmacology

Bethanidine is a post-ganglionic adrenergic neurone-blocking agent which exerts a marked postural hypotensive effect (Boura *et al.*, 1961; Boura and Green, 1963; Fewings *et al.*, 1964). In man sympathetic blockade begins about two hours after a single dose, is maximal in four to five hours, and fades in 8 to 12 hours, but the duration of action depends on the dose administered (Smirk, 1963; Johnston *et al.*, 1964; Wilson *et al.*, 1965). The absorption and excretion of ¹⁴C bethanidine in man was studied by Doyle and Morley (1965), who showed that after oral administration absorption was rapid and almost complete. Excretion is almost entirely in the urine, the rate depending on the glomerular filtration rate. Other studies have shown the renal clearance of inulin and of para-aminohippuric acid to be slightly reduced in patients given bethanidine (Esch and Krammer, 1965).

The precise mechanism whereby bethanidine causes blockade of adrenergic neurones is unknown (Boura and Green, 1965). An initial sympathomimetic effect has been demonstrated in man and animals, possibly due to release of catecholamines, for it is blocked by phenoxybenzamine (Fewings *et al.*, 1964), and increased sensitivity to noradrenaline after bethanidine further suggests peripheral release of catecholamines by this drug. Bethanidine resembles bretyliumtosylate and debrisoquine in that blockade is achieved without early depletion of tissue catecholamines, in this respect differing from guanethidine and guanoclor. However, large doses of bethanidine over long periods reduce catecholamines in some tissues (Boura *et al.*, 1961). Unless administered in very high concentration bethanidine does not block cholinergic or motor-neurone activity (Boura and Green, 1963).

Material and Methods

Between September 1964 and March 1967 70 patients were treated with bethanidine for periods ranging from six to 24 months: 23 were followed up for six to 12 months, 10 for 13 to 18 months, 22 for 19 to 24 months, and 15 for 25 to 30 months. In addition 12 patients stopped treatment earlier for reasons discussed below. Ages ranged from 21 to 66 years. Of the 82 patients 41 were male and 41 female. Table I includes the age distribution related to severity of the disease.

Indications for treatment, selection of patients, methods of blood pressure measurement, criteria of severity, and classification of results were similar to those we have already described in relation to the other drugs except that this series includes more relatively young patients without evidence of secondary changes in the heart or fundi.

Half the patients had previously received treatment with other antihypertensive drugs. Most new patients were admitted to hospital for assessment of the severity and type of their hypertension and the initiation of appropriate treatment. In some who had been fully assessed previously and treated for

a period with other drugs the change-over was arranged on an outpatient basis. The usual reason for change was difficulty in controlling the blood pressure, undue postural hypotension, or side-effects.

TABLE I.—Clinical Features

	Severe Hypertension	Moderate Hypertension	Total

Grade I-II	21	27	48
Grade III	15	5	20
Grade IV	3	0	3
Resting diastolic pressure before treatment:			
105-129 (mm. Hg)	15	22	37
130-149	18	14	32
150+	6	7	13

The initial dose of bethanidine was usually 5 mg. twice daily. Increments were made every third day in hospital patients and every week in those being treated at home until an adequate response was obtained. Frequency of attendance at the clinic depended on the degree of control or the presence of side-effects. The daily dose ranged from 10 to 120 mg., with an average of 32.5 mg. in the initial stages and 43 mg. later on.

As in previous studies of antihypertensive drugs the aim of treatment was to reduce the standing diastolic pressure to as near normal levels as could be achieved without undue side-effects. In patients with cerebral or coronary atherosclerosis or with a persistently raised blood urea the blood pressure was lowered more cautiously and reduction to a standing diastolic level of 100-105 mm. Hg was regarded as a satisfactory result. Only the fall in pressure achieved and maintained has been considered in classifying the results of treatment. A "good" result signifies a fall in diastolic pressure to below 100 mm. Hg. A "fair" result signifies a fall of diastolic pressure to between 100 and 110 mm. Hg. A "poor" result denotes failure to maintain a diastolic pressure below 110 mm. Hg. It will be appreciated that a precise classification is not possible because in some patients the deliberate aim has been to achieve a fair result as defined by reduction in blood pressure.

The results have been tabulated for each patient at intervals of six months.

Results

Of the original 82 patients, four died, seven discontinued bethanidine because of side-effects, and one defaulted before the end of six months. The remaining 70 all completed at least six months of treatment (Table II).

After six months one patient discontinued the drug because of side-effects, two defaulted, and seven died. At the end of

	Fair	3	1	4	27
	Poor	1	1	2	13

six months 73% of patients had good or fair control of their blood pressure. Results improved with continued treatment and adjustment of dosage with or without the addition of an oral diuretic, the proportion having good or fair control rising to 80% after 12 months and to 87% in the 15 patients who had been treated for two years. Most of the poor results were in patients with severe hypertension.

Of the 19 patients in whom initial control was unsatisfactory 13 continued treatment for 12 months or more. Good or fair control was achieved in five by increasing the dose and in three more by the addition of an oral diuretic. Of the five patients in whom control was persistently poor two had severe cerebral atherosclerosis, one uraemia, one asthma requiring corticosteroid therapy, and one cor pulmonale. Temporary failure of control was attributed to tolerance in two patients and to side-effects in two others. Of nine patients with only fair control throughout, two had severe cerebral atherosclerosis, five side-effects, and one a rising blood urea.

Deaths

Eleven patients died during treatment, but in none was this thought to be attributable to the drug being used or to failure to maintain reasonable control over the blood pressure or to side-effects. Three died from myocardial infarction, three from cerebral haemorrhage, and two from uraemia. In addition, one died from rupture of an aortic aneurysm and one suddenly from an unknown cause.

Four patients had been under treatment for three months or less, four for 8 to 14 months, and three for approximately 18 months. Seven had previously shown evidence of coronary or cerebral atherosclerosis.

Side-effects

Thirty-one patients (38%) had symptoms from postural hypotension, but in most cases this was relieved by adjustment of dosage while still maintaining satisfactory control over the blood pressure. A few had syncope and in five bethanidine had to be discontinued.

As is usual with drugs which lower blood pressure by sympathetic blockade the lowest readings were recorded first thing in the morning or when special readings were taken during what are normally sleeping hours. It is of interest in this connexion that several patients complained of syncope or dizziness after rising at night to pass urine.

Transient focal neurological disturbances associated with postural hypotension were recorded in two patients, but in none of the six whose death was attributable to a cerebral vascular accident or in the two patients who died of renal failure had there been excessive hypotension.

Five patients complained of muscular weakness soon after starting treatment and in two the drug was discontinued. Two who complained of impotence had previously experienced this symptom when taking other antihypertensive drugs. There was no case of diarrhoea or of mental depression. Two patients developed cardiac failure while on treatment, but this was attributable to the underlying heart disease.

The incidence of side-effects bore no obvious relation to the initial severity of hypertensive disease, the presenting symptoms, associated atherosclerosis, the degree of blood pressure control, or subsequent death. As with other antihypertensive drugs the incidence between individuals was most variable.

Oral Diuretic Supplements

In order to facilitate comparison with other drugs it had been intended, if possible, to treat all patients with bethanidine alone. However, it became necessary to add an oral diuretic in 28 cases on account of difficulty in controlling the pressure, side-effects, or fluid retention.

As can be seen from Table III the mean daily dose of bethanidine was gradually increased for most patients. In 19 cases the dose was increased to improve control and in seven to regain control on account of tolerance. An oral diuretic was added to improve control in six and to regain control in two patients. The fact that supplementary oral diuretics were used in 34% of all patients reflects the difficulty experienced in achieving satisfactory control with freedom from excessive postural hypotension when using bethanidine alone. In a few cases a diuretic was used from the start because rapid control of the blood pressure or a diuresis was required. Diuretics were used in a proportionately larger number of patients the longer treatment continued, because of an increased tendency to make this addition whenever difficulty with control or side-effects was experienced.

TABLE III.—Average Dose of Bethanidine According to Duration of Treatment

Duration of Treatment (months)	No. of Patients	Average Dose Bethanidine (mg.)
3	77	32.5
6	70	37
12	47	40
18	37	43
24	15	45

Comparison of Guanethidine, Methyldopa, Debrisoquine, and Bethanidine

Since the treatment of hypertension with guanethidine, methyldopa, and debrisoquine has previously been described from our unit some comparison between these drugs can be made. Recently, however, there has been a decreased incidence of severe hypertensive disease and a progressive tendency to treat patients who have relatively mild hypertensive disease. It is no longer thought desirable to carry out double-blind trials of different drugs in the same patient because of greater ease of controlling the blood pressure. All that is required is to change treatment to another preparation in any patient not doing well on a particular drug.

Table IV shows the results of treatment in groups of patients thought to have hypertensive disease of comparable severity according to the criteria described. Seventy-three with severe hypertension were treated with guanethidine, 37 with methyldopa, 31 with debrisoquine, and 26 with bethanidine, all for more than six months and many for as long as 18 months. The same criteria were used in classifying results on the basis of blood pressure control. It will be seen that there is no striking difference in the results of treatment with the four

TABLE IV.—Comparison of Long-term Results and Supplementary Use of Oral Diuretics in Treatment of Severe Hypertension with Guanethidine, Methyldopa, Debrisoquine, and Bethanidine

Control	Guanethidine 73 Patients	Methyldopa 37 Patients	Debrisoquine 31 Patients	Bethanidine 26 Patients
Good ..	40%	54%	71%	70%
Fair ..	40%	33%	22%	15%
Poor ..	20%	13%	7%	15%
Supplementary diuretics ..	56%	41%	65%	38%

preparations. About 50% of patients on guanethidine, about 40% each with methyl dopa and bethanidine, and about 65% with debrisoquine, required the addition of an oral diuretic. This probably reflects a somewhat greater degree of tolerance to debrisoquine, but on the other hand, as discussed below, postural symptoms and side-effects were least with this preparation.

Discussion

The rapid onset of the antihypertensive effect after oral administration of bethanidine and the short duration of action are obvious advantages when reduction of blood pressure is required as an emergency or when an excessive hypotensive effect has to be counteracted quickly. In the two instances in which we have used oral bethanidine to gain rapid control of malignant hypertension a satisfactory response was obtained within the first 24 hours.

In long-term treatment fair or good control was obtained in 73 to 87% of patients, depending on the duration of treatment. These results are similar to those reported by Montuschi and Pickens (1962), who used supplementary oral diuretics in over half their patients, and by Johnston *et al.* (1964), who used oral diuretics in less than 20% of cases. In the report by Smirk (1963) the assessment of results was rather different, but approximately 60% of 56 patients were controlled with bethanidine alone. Esch and Krammer (1965) obtained a satisfactory result in 35 out of 40 outpatients, using supplementary oral diuretics only occasionally.

The chief difficulty we have encountered is postural hypotension, which is most likely to occur in the initial phases of treatment when quite pronounced fluctuations of standing blood pressure may occur. Postural symptoms may be particularly troublesome in the morning, and in those who for any reason have to get out of bed at night. The fall in pressure which follows micturition may be an additional factor in some cases. Postural hypotension is also particularly apt to develop after the addition of an oral diuretic unless care is taken to make an adequate reduction in the dose of bethanidine. We have the impression that this may occur more readily than with other antihypertensive drugs but that smoother control may sometimes be achieved by suitable timing of the doses of bethanidine given three or four times during the 24 hours, depending on individual requirements. Since bethanidine has considerable advantages in other respects persistence is well worth while because satisfactory control can usually be achieved.

Possibly each patient should first be treated for three to four weeks with an oral diuretic, after which time it is known that there is no further reduction in exchangeable sodium and that plasma and extracellular fluid volumes rise to previous levels, though the antihypertensive action of the diuretic persists (Peters, 1966).

However, the long-term administration of oral diuretics in the treatment of hypertension depletes the body not only of sodium but of potassium and other ions, including magnesium, so that many would prefer not to use them routinely. In all cases it is only sensible to reduce the intake of salt.

The dose of drug required to maintain control increased in many patients after they left hospital, but tolerance with bethanidine is not a serious problem and can always be overcome. After three to six months, when smooth control had been obtained, a further increase in dosage or the addition of an oral diuretic was required in about one-third of patients, but increments were usually small and after 18 months the need for a further increase was exceptional. It would therefore appear that tolerance is less of a problem in long-term management of hypertension with bethanidine than with debrisoquine. On the other hand, good control of the blood pressure during the first six months of treatment was achieved in a higher proportion of patients with debrisoquine and there was a lower incidence of side-effects. If in the first few months

control can be achieved with bethanidine without undue postural effects it is likely to remain satisfactory.

In our experience the disadvantages of guanethidine included the difficulty in adjustment of dosage because increments were so critical, the frequency and disabling nature of side-effects, postural hypotension and syncope of effort, and the development of tolerance. With methyl dopa side-effects were usually milder and less persistent, but many patients did not feel well; also a number of severe toxic effects have now been reported, including Parkinsonism, hyperpyrexia, jaundice, and haemolytic anaemia.

Tolerance with debrisoquine and postural hypotension with bethanidine are relative disadvantages but less troublesome and disabling than the difficulties encountered with guanethidine or methyl dopa.

There would now seem to be no case for beginning treatment with guanethidine or methyl dopa in any new patient, but either may be useful in any patient in whom treatment with one of the newer preparations is unsatisfactory.

There can be no question that with the principal antihypertensive drugs in common use today, and with due attention to detail, the blood pressure can almost always be controlled satisfactorily, but some patients do better on one preparation than on another. It may be that instead of adding an oral diuretic there should be greater experiment with drugs in combination, and if any individual patient is not doing sufficiently well on debrisoquine or bethanidine a combination of these two preparations may well prove effective. Further experience is clearly required.

Summary

Seventy patients with hypertension were treated with bethanidine for periods ranging from six months to two years with satisfactory control of the blood pressure in about three-quarters of them.

Toxicity was not seen and side-effects, apart from postural hypotension, were rare. Tolerance was not a problem.

Postural symptoms were experienced by 38% of all patients but could usually be overcome by adjustment of dosage and timing of drug administration or by combination with an oral diuretic.

For various reasons an oral diuretic was added in 34% of cases.

An attempt was made to compare the efficacy of guanethidine, methyl dopa, debrisoquine, and bethanidine in groups of patients of similar severity as regards hypertensive disease.

It is concluded that bethanidine is a most useful addition to the drugs available for the treatment of hypertension, and, like debrisoquine, has advantages which outweigh relative disadvantages in comparison with guanethidine or methyl dopa.

We thank Dr. N. L. Stokoe for reports on the retina of these patients; Miss M. Baker and Mrs. S. Heggie for carrying out numerous blood pressure readings; and Dr. A. D. Munro-Faure, of the Wellcome Foundation, for pharmacological advice.

Detection of Carriers of Benign X-Linked Muscular Dystrophy

ALAN E. H. EMERY,* M.D., M.Sc., Ph.D., M.R.C.P.Ed.; ENID R. CLACK†; SYBIL SIMON,‡ M.B.
JOHN L. TAYLOR,§ M.B., B.Sc., M.R.C.P.

Brit. med. J., 1967, 4, 522-523

From the point of view of genetic counselling carrier detection is most important in X-linked disorders. Okinaka *et al.* (1959) were the first to employ the serum level of creatine kinase to detect female carriers of X-linked Duchenne muscular dystrophy. Since then many investigators have confirmed the usefulness and reliability of this test. So far results on over 200 carriers have been reported, and of these approximately two-thirds were found to have significantly raised levels of serum creatine kinase (Emery, 1967).

Besides the severe Duchenne type of muscular dystrophy, another X-linked form of muscular dystrophy has been recognized by Becker (1955, 1957, 1962). This type of muscular dystrophy is clinically similar to Duchenne muscular dystrophy in that weakness begins in the pelvic girdle musculature, only later affecting the upper limbs, and there is pseudohypertrophy of the calf muscles. However, it differs from Duchenne muscular dystrophy because the disease does not manifest itself until the teens or early twenties, and affected individuals usually become chair-ridden only after 25 to 30 years. This report is concerned with the usefulness of serum enzyme studies for detecting carriers of this benign Becker type X-linked muscular dystrophy.

Subjects and Methods

Carriers.—All the carriers belonged to four large families, in each of which were several affected males. A definite carrier has been defined as a daughter of an affected man or a woman with an affected son and a family history of other male relatives having been similarly affected—for example, a brother or maternal uncle.

Controls.—Enzyme determinations were carried out on 50 normal women with no history of any neuromuscular disease and of comparable age to the carriers.

Methods.—Blood samples were taken during everyday activity. In most cases enzyme determinations were carried out within an hour or so of the blood sample being taken. In the few instances where this was not possible the serum was frozen and kept at -20°C . until the following day. No specimens were stored for more than 24 hours. Serum levels of creatine kinase were estimated according to the method of Tanzer and Gilvarg (1959), using a Hilger and Watts Uvispek spectrophotometer with temperature control. Cysteine was incorporated in the reaction mixture to a final concentration of $1\text{ }\mu\text{M}/\text{ml}$. The incorporation of cysteine has been shown to increase the accuracy and reproducibility of assay methods for serum creatine kinase and to prevent the loss of enzyme activity which occurs when serum is stored (Hughes, 1962; Okinaka *et al.*, 1964; Kar and Pearson, 1965; Finley and Anderson, 1966). With cysteine incorporated in the reaction mixture the values obtained were not appreciably affected by storing serum samples for

several days at -20°C . However, without cysteine the values obtained after storage were significantly less than those obtained with fresh serum. It would seem, therefore, that if stored serum is used cysteine should be incorporated in the reaction mixture.

Results are expressed in international units, one unit being that amount of enzyme which catalyses the transformation of $1\text{ }\mu\text{M}$ of creatine per 1,000 ml. of serum per minute at 25°C . and pH 9. Duplicate determinations were carried out on each sample of serum.

Results

The values for the serum levels of creatine kinase in the controls were not normally distributed, but the cumulative

FIG. 1.—Serum creatine kinase levels in controls and carriers, actual values.

FIG. 2.—Serum creatine kinase levels in controls and carriers, cumulative percentage frequency of the logarithms of the values.

§ Consultant Physician, the Infirmary, Rochdale, Lancs.

distribution produced a close approximation to a straight line on a log. probability plot, and from this curve the normal 95 percentile was estimated to 3.5 units. Of the 26 definite carriers who have been tested 13 (50%) had serum levels of creatine kinase which exceeded the normal 95 percentile (Fig. 1). From the cumulative log. probability plot approximately 48% of carriers would be predicted to have values more than 3.5 units (Fig. 2). There was no significant correlation ($r = +0.04$) between age and the serum level of creatine kinase.

Enzyme determinations were carried out on 14 possible carriers. These were women who were sisters of affected males, sisters of definite carriers, or daughters of definite carriers. Except for two boys who were not available for testing, all the sons of these possible carriers were examined and their serum level of creatine kinase was determined, but none was found to be affected. Five (36%) of these possible carriers had raised serum creatine kinase levels.

None of the 26 definite carriers or any of the 14 possible carriers had enlarged calves or any evidence of muscle weakness.

Discussion

A benign form of X-linked muscular dystrophy was first recognized by Becker (1955, 1957, 1962). Other investigators have also reported families in which the onset was later and the progression slower than in the classical X-linked Duchenne

Serum Creatine Kinase in Carriers of Benign X-linked Muscular Dystrophy

type of muscular dystrophy (Levison, 1951; Lamy and de Grouchy, 1954; Walton, 1955-6, 1956-7; Blyth and Pugh, 1958-9; Emery, 1964; Rotthauwe and Kowalewski, 1966a). Mabry *et al.* (1965) and Emery and Dreifuss (1966) have described families with benign forms of X-linked muscular dystrophy which appeared to differ clinically from the Becker type, and these investigators have suggested that there may be at least three different types of benign X-linked muscular dystrophy.

So far there have been few published reports of serum enzyme studies in carriers of benign X-linked muscular dys-

trophy (see Table). The findings of the present study are in good agreement with those of Rotthauwe and Kowalewski (1966b) in showing that approximately 50% of carriers have significantly elevated levels of creatine kinase. The test may therefore be useful in genetic counselling in this form of muscular dystrophy.

Summary

The serum level of creatine kinase has been found to be significantly elevated in 13 out of 26 (50%) definite carriers and 5 out of 14 (36%) possible carriers of benign (Becker type) X-linked muscular dystrophy. The test may therefore be useful in genetic counselling in this form of muscular dystrophy.

Grateful thanks are due to Dr. J. Timson and Dr. D. Gardner-Medwin for valuable help in tracing members of certain families and to Miss Valerie Hodson for technical assistance. The work was supported by a research grant from the Muscular Dystrophy Group of Great Britain. S. S. was in receipt of an M.R.C. research scholarship.

Congenital Phocomelia in Monozygotic Twins

S. G. I. HAMILTON,* M.A., M.CHIR., F.R.C.S.

Brit. med. J., 1967, 4, 524-526

Phocomelia is the congenital absence of legs and arms, resulting in the hands and feet being in close proximity to the trunk. Occasionally deformed intermediate segments may be demonstrated radiologically (Carey, 1919), though the limb girdles and digital elements may appear normal.

In the past decade interest has been taken in abnormalities showing phocomelia as a result of thalidomide taken by the mother during pregnancy. It has been shown (Lenz and Knapp, 1962) that a critical period of sensitivity, 34 to 50 days after the last menstrual cycle or 20 to 36 days' ovulation age, exists in the human in those cases having thalidomide deformities. These results have recently been reproduced in mammals, including primates (Hendricks *et al.*, 1966).

Similar defects are known to have existed many years before the use of this drug. Two paintings, one entitled *Handschriften* depicting the armless town clerk of Nuremberg at the end of the sixteenth century (Oertel, 1962), and the other by Goya in the Louvre (Smithells, 1966), must surely refer to the same defect.

The case discussed below is unrelated to thalidomide therapy, though the deformity, particularly of the arms, resembles in many respects that seen after thalidomide therapy.

Case Report

A married woman aged 30 had a history of primary infertility of five years' standing and was found on examination to have an enlarged, blocked left uterine tube. Radiology was not undertaken during the pregnancy, and only routine investigations had been made previously.

History of Pregnancy.—Tubal insufflation was carried out three weeks after a normal menstrual period. No further vaginal loss

occurred until the fourteenth week of her pregnancy, when she had a threatened miscarriage. She was found to be group O Rhesus-negative with no antibodies. A normal pregnancy persisted until 38 weeks, when mild pre-eclampsia developed, but still no antibodies were present. She was treated by bed rest, and was admitted to hospital in labour at 39 weeks. She had an assisted vaginal delivery of stillborn malformed "locked twins," sharing a single placenta.

Description of Twins (Fig. 1).—Both twins were male. Twin 1 showed a normal head and trunk. The hands were set directly into the shoulder region, both appearing like flippers with no division into fingers. The feet were appended to the lower end of the trunk and pointed laterally. The right and left feet had five toes each. Twin 2 had a normal head and trunk, but there was a complete absence of arms. The feet were attached directly on to the lower end of the trunk and showed division into toes: six on the right foot and only four on the left foot. **Radiologically** their appearance was stated as follows. **Twin 1** (Fig. 2): The skull, vertebrae, ribs, and pectoral girdle are normal. There is complete absence of any bone in the upper limbs apart from a metacarpal and phalanx representing one digit. The pelvic girdle is normal. The lower limb skeleton is represented only by a talus, a calcaneum, and metatarsals and phalanges of five digits on each foot. **Twin 2** (Fig. 3): Again the skull, vertebrae, and ribs are normal. The pectoral girdle is normal, with complete absence of any upper-limb skeleton. The pelvic girdle is normal. The lower limb shows only the presence of a talus, a calcaneum, and six metatarsals and phalanges on the right side, and a talus and four metatarsals and phalanges on the left side.

Development of Limbs.—Limb buds in the human make their appearance at about 30 to 32 days' estimated age, 28 to 30 somite stage, or 5 mm. crown-rump length, and the digits at a later stage (40 mm. crown-rump length) (Fig. 4). The arm buds appear opposite the fifth to seventh cervical somites at the level of the pericardial swelling and the leg buds appear some 48 hours later opposite the second lumbar to the third sacral segments and lie just caudal to the attachment of the umbilical cord. The first evidence of a limb bud is of a condensation of mesenchymal cells, showing frequent mitotic figures in the body wall, throwing up a slight

FIG. 1.—Twins 1 (left) and 2 (right) showing limb deformities.

FIG. 2

FIG. 3

FIG. 2.—Radiograph of Twin 1, showing normal pectoral and pelvic (rotated) girdles. FIG. 3.—Radiograph of Twin 2.

* Senior Registrar, Royal Devon and Exeter Hospital, Exeter, Devon.

longitudinal ridge on the surface of the embryo. At the apex of this condensation the ectoderm is thickened (Fig. 5)—the apical ectodermal ridge (Boyd, 1960). In the mesenchymal tissue vasculogenesis occurs, forming a fine-meshed plexus between the cells, tapping the segmental artery at the base of the limb bud and draining into a marginal vein. All the structures of the limb are derived from the ectodermal and mesenchymal cells of the limb bud except the nerves, pigment cells, and possibly the larger vessels. Except for these structures the limb is a "self-differentiating system."

The limb buds develop before there is any differentiation of anterior horn cells in the spinal cord, and in one case (Curtis and Helmholtz, 1911) there was no cervical enlargement and no lateral portion of the anterior horn cells.

Experimental Embryology

Most experimental work on limb development has been performed on amphibians and birds, though similar processes have been shown to exist in mammals (Milaire, 1965).

FIG. 4.—Photograph of a portion of a human embryo (10 mm. crown-rump length) to show the development of a limb bud. Note the peripheral sinus around the tip of the limb bud.

It would seem that for normal limb growth to occur both limb mesenchyme and an apical ectodermal ridge must be present, and the latter's persistence depends on a "maintenance factor" from the mesenchyme, distributed asymmetrically. Abnormal development may thus result from interference with this "inductive" mechanism either by loss of capacity for inducing or loss of response from the subjected tissue, or failure of the one from reaching and reacting with the other (Beck and Lloyd, 1966). Of the experiments leading to this conclusion one appears to be pertinent in the present context: if *non*-limb mesenchyme is covered with limb ectoderm, including the apical ridge, the structure so formed does not develop into a limb, but if a fragment of limb mesenchyme is introduced beneath the ectodermal jacket at the apical ridge the latter maintains its thickened structures and an elongated outgrowth forms (Zwilling, 1956). The mesenchyme acts, therefore, as an inductor force on only a limited area of the ectodermal ridge and is insufficient in capacity to cause the formation of a normal limb.

Normally development progresses in a proximo-distal differentiation, and in bilateral organs this differentiation may occur at slightly different times, giving a discrepancy in size between the two sides (Stockard, 1931).

Discussion

Much attention has been focused recently on the effect of drugs, particularly thalidomide, on limb skeletal abnormalities. The twins described were born after a pregnancy in which no drug therapy had been employed, no fever had interrupted, and only possible hypoxia as a result of insufflation and perhaps temporary disestablishment of implantation had resulted. Several cases have been mentioned, and six patients who have

FIG. 5.—Photomicrograph of a longitudinal section of a human limb bud to show the apical ectodermal proliferation.

appeared since the withdrawal of thalidomide are at present alive and under treatment (E. P. Quibell, personal communication, 1966).

It is suggested that the formation of the deformity of phocomelia may result in one of two ways. (1) Some agent damages the proximal mesenchymal cells after they have been separated from the subapical mesenchymal cells, and that these latter, provided the damaging agent is no longer functional, may then give rise to normal distal limb elements. (2) It has been shown that mesenchymal cells destined to become thigh, if placed under the apical ridge, may form digits (Saunders *et al.*, 1957). It may be that the destructive agent damages the distal mesenchymal cells, and, by leaving the proximal mesenchymal tissue under the apical ectodermal ridge, these cells now differentiate into digits. Such a deleterious agent is thalidomide, and it has been shown (Lenz and Knapp, 1962) that there is only a limited period of development when such an agent may act to produce this effect.

It would seem that a number of teratogenic agents may exist, and that drug therapy, though bringing the subject to the forefront, is not the only cause for the development of such abnormalities.

Summary

The occurrence of phocomelia in monozygotic twins other than that resulting from thalidomide therapy is described. The exact way by which the anomalies are produced is not known, though two possible mechanisms are discussed in the light of experimental embryology and the development of the normal human limb bud.

The critical time in pregnancy for such defects to be produced varies for upper and lower limbs between narrow limits, and the rate of growth and the stage of development of one

of the twins described comparable to the other emphasize the variability of the abnormality.

I wish to thank Mr. D. M. W. Maxwell, of Windsor, for allowing me to examine these twins and for permission to report on them.

ABO Blood Groups and Polyps of the Colon*

THOMAS C. FLEMING,† M.D.; HARVEY W. CAPLAN,‡ M.D.; GEORGE A. HYMAN,§ M.D.
F. DAVID KITCHIN,|| M.D., M.R.C.P.

Brit. med. J., 1967, 4, 526-527

Though it appears that a significant proportion of villous adenomas or papillomas of the large bowel develop malignant properties, the debate still continues on the importance of adenomatous polyps as the sources of large-bowel cancer. Evans (1966) feels that the associations between multiple cancers of the colon and adenomatous polyps, and multiple polyps and cancer of the bowel, do not necessarily indicate an orthogenetically determined polyp-carcinoma sequence. He favours the view that they represent varying degrees of genetically determined large-bowel proneness to both cancer and adenoma.

With the exception of polyposis coli, no genetic locus has been associated with cancer of the large bowel or polyp formation, though Veale (1965) has postulated an unfavourable allelic modifier of the polyposis gene which in double dose produces a few adenomas of the rectum or colon. The ABO locus which is implicated in the causation of cancer of the stomach (Aird *et al.*, 1953), multiple primary cancers (Fadhli and Dominguez, 1963; Tsudaka *et al.*, 1964), and possibly chronic lymphatic leukaemia or lymphoma and carcinoma of the colon (Hyman *et al.*, 1963), does not appear to be a factor in carcinoma of the colon.

This paper reports the ABO blood group distributions in 373 patients with polyps of the colon or rectum and an association between group O and papillary adenoma of the colon.

Materials and Methods

Case records of all patients seen at Columbia-Presbyterian Medical Center between 1948 and 1960; at Montefiore Hospital, Bronx, N.Y., between 1952 and 1959; and at the Bronx Veterans Hospital, Bronx, N.Y., between 1952 and 1959 who had the diagnosis of polyps of the colon or rectum were

checked. Only Caucasian patients whose blood types were known and whose polyps were removed and examined histologically were selected, and any family history of polyps or of carcinoma was carefully noted. For all cases from this centre the ABO blood groups were determined in the Presbyterian Hospital Blood Bank and were done on admission before transfusion. The cases totalled 317 from Columbia-Presbyterian Medical Center, 22 from Montefiore Hospital, and 34 from the Veterans Hospital. Follow-up was not complete, but 90% (335) of the patients were examined by barium meal, proctoscopy, or both to determine whether carcinoma or additional polyps had developed. During a five-year follow-up 58% (217) of the patients were seen several times. Patients were assigned to groups depending on pathological diagnosis, the number of polyps, and the family history.

For the purposes of this study adenomatous polyps are defined as being composed of a rounded, lobulated compact mass of branching glandular tubules, lined by columnar epithelium and supported by branching connective tissue. They are usually pedunculated, with the pedicle covered by normal mucosa (Grinnell and Lane, 1958). Papillary adenomas are defined as sessile growths, composed of innumerable branching villi clothed in stratified or pseudostratified columnar epithelium and usually covered by a coating of mucus (Grinnell and Lane, 1958).

Case records of all patients seen at Columbia-Presbyterian Medical Center between 1930 and 1966 with the diagnosis of polyposis of the colon, defined as 10 or more polyps, were checked. Of the 18 cases found 12 were examples of intestinal polyposis and seven had a positive family history. All patients with polyposis coli had their colon removed surgically and were found to have large numbers (from hundreds to thousands) of adenomatous polyps. The six patients with as few as 10 polyps have been included in the multiple polyposis group because it is thought by some (Veale, 1965; McConnell, 1966) that these patients may have inherited a weakly expressed polyposis gene.

As most of the patients were treated at the Columbia-Presbyterian Medical Centre the control group was chosen from this hospital's blood bank records. Non-profit Caucasian donors at the Presbyterian Hospital Blood Bank for the year 1960 were decided to be the most appropriate control, since the few Negroes with polyps were excluded from the study. In spite of careful selection there was a higher incidence of group B and a lower incidence of group A in the Presbyterian Hospital series than in other control groups (see Table I). This

finding may be the expression of bias inherent in a non-profit donor group which is composed of friends and relations replacing blood used in the treatment of one of their family as well as public-spirited blood donors. Nevertheless, when this control group is compared, O to Not-O, with the pooled control groups from other regions in the U.S.A. the heterogeneity test gives $\chi^2=0.114$; $0.80>P>0.70$, and so the smaller control group has been used for the comparisons.

TABLE I.—ABO Blood Groups in Control Caucasian Populations

Group	A	B	O	AB	Total
Caucasian non-profit donors at Presbyterian Hospital in 1960 (group chosen as overall control)	928 36.8%	344 13.6%	1,122 44.4%	131 5.2%	2,525

TABLE III.—Statistical Analysis

Comparison O/Not-O	χ^2	Degree of Freedom	Significance
A. All polyps/control ..	0.261	1	0.70 > P > 0.60
B. Adenomatous/control polyps ..	0.378	1	0.60 > P > 0.50
C. Papillary adenomatous/control ..	8.496	1	0.005 > P > 0.001
D. Papillary/control adenomatous polyps ..	3.046	1	0.10 > P > 0.05
E. Groups C and D/control ..	10.432	1	0.005 > P > 0.001
F. Polyposis coli/control ..	2.012	1	0.20 > P > 0.10

A. Three hundred and seventy-three patients had one or more polyps, and there was no statistical difference in the distribution of blood groups between these and the controls.

B. Three hundred and twenty-six patients had one or more adenomatous polyps, and there was no statistical difference in the distribution of blood groups between these and the controls.

C. Twenty-one patients had one or more papillary adenomas, and 16 (76%) of these were blood group O. This increase was statistically significant ($P>0.001$) when compared with the control group.

D. Twenty-six patients had both papillary adenomas and adenomatous polyps, and 16 (62%) of these were type O. This finding was not statistically significant.

D

E. Groups C and D can be combined (heterogeneity test C+D gives $\chi^2=0.57$, $0.50>P>0.40$) to make a group of 47 patients, all of whom had at least one papillary adenoma. Thirty-two (68%) of these patients were group O, and this finding was significant ($P<0.005$). If the combined control group from other regions in the U.S.A. is used for comparison $\chi^2=10.958$, $P<0.001$.

F. Eighteen patients had multiple polyposis, and 11 (61%) of these were type O, but this increase was not statistically significant.

G. Only 16 of 373 patients with polyps had a family history of colonic carcinoma or polyps of the colon. Two of these had multiple polyposis and 13 had one or more adenomatous polyps.

Discussion

Analysis of the data indicates that the ABO blood group distributions in patients with polyps of the colon are not significantly different from control populations except in the subdivision of papillary adenomas.

The data suggest that papillary adenomas can be distinguished from adenomatous polyps, familial and non-familial, since the ABO locus is involved in the papillary adenoma group. Furthermore, this finding indicates that papillary adenomas have a different cause from adenomatous polyps in that the ABO locus is one of the polygenic factors conditioning the susceptibility to the disease.

The limitation of a study of this type is well recognized, particularly in view of the small number of patients and difficulty in selecting a proper control group because of the racial differences in blood type in the heterogeneous population of New York City. We hope that this study will stimulate further investigations of the ABO blood groups in patients with papillary adenomas and adenomatous polyps of the colon in other populations.

Summary

The ABO blood groups have been determined in 373 patients with polyps of the colon, divided into adenomatous polyps and familial and non-familial and papillary adenomas. In the two subdivisions of the adenomatous polyps the blood group distributions did not differ from the control group, but a significant excess of blood group O was found in the patients with papillary adenomas. This finding indicates that papillary adenomas have a different cause from adenomatous polyps and supports the separation, on histological and clinical grounds, of the two kinds of growths.

We wish to thank the following colleagues in Columbia University College of Physicians and Surgeons for their invaluable assistance in the preparation of the manuscript: Dr. Nathan Lane and Dr. Rafael Lattes, Department of Surgical Pathology; and the staff of the Department of Statistics, Columbia University School of Public Health. We also wish to thank the Record Departments of the Montefiore and Bronx Veterans Hospitals for their assistance during the performance of the studies.

Preliminary Communications

Influence of Glucose and Insulin Administration on the Achilles Tendon Reflex Time

Brit. med. J., 1967, 4, 528-529

The Achilles tendon reflexogram or photomotogram has long been used in the diagnosis and follow-up of thyroid disorders. While an extensive literature exists on this subject, only a few investigations have been carried out concerning the relations between the Achilles tendon reflex time and carbohydrate metabolism. First, it was observed that Achilles tendon areflexia may occur in diabetic patients (Ellenberg, 1961; Krosnick, 1964). Subsequently it was reported that the reflex time is prolonged in diabetes (Beardwood and Schumacher, 1964; Kissel *et al.*, 1966). In our experience, too, the reflex time is generally prolonged in diabetic children, but the degree of prolongation is related neither to the severity or duration of the disease nor to the adequacy of treatment, and it may change from day to day. As pointed out by Beardwood and Schumacher (1964), neuropathy as an explanation for this phenomenon seems therefore unlikely. In an effort to elucidate a possible relation between carbohydrate metabolism and the Achilles tendon reflex time we have carried out the studies presented in this preliminary communication.

METHODS

Five adult subjects in good health (two males, three females), aged 24 to 43 years, were studied. None had a history of thyroid dysfunction or diabetes mellitus.

In each subject an intravenous glucose-tolerance test (15 g. glucose per sq. m. surface area) and, with an interval of several days, an intravenous insulin-tolerance test (4 units insulin (Actrapid Novo) per sq. m. surface area) were performed after an overnight fast. Blood glucose concentration in capillary blood was determined by the colorimetric glucose oxidase assay (reagents C. F. Boehringer GmbH Mannheim, Germany) at 0,

15, 30, 45, 60, 90, and 120 minutes after injection. At each of these times Achilles tendon reflexes from the same leg were recorded with a Burdick photomotograph. Thirty or more reflexes were recorded at each time. All photomotograms were measured by the same person without knowledge of the time of the tolerance test when they were recorded. The values expressed in milliseconds represent the mean time between the hammer tap and one-half relaxation from 30 to 40 technically satisfactory recordings. The standard deviations at any time of the glucose- or insulin-tolerance test ranged from 9 to 16 msec. The normal range for adults is 260 to 380 msec.

In one subject the insulin-tolerance test was repeated, but immediately before the injection of insulin an adrenergic β -receptor antagonist (propranolol, 0.15 mg./kg. body weight) was given intravenously (Abramson *et al.*, 1966). Blood glucose concentrations and half relaxation time were then determined in the same way as in the other experiments.

RESULTS

The results are summarized in Figs. 1, 2, and 3. In all subjects the mean half relaxation time increased during the glucose-tolerance test (Fig. 1). The longest mean half relaxation time was reached between 45 and 120 minutes after glucose administration, thus considerably later than the peak glucose concentration, which was always observed 15 minutes after glucose administration. The increase ranged from 12 to 18% of the mean half relaxation time at 0 minutes.

In all subjects the mean half relaxation time decreased during the insulin-tolerance test (Fig. 2). In contrast to the delay of the maximum half relaxation time during the glucose-tolerance test, the minimum half relaxation time was found here at the same time as or only 15 minutes after the minimal blood glucose concentration. The decrease ranged from 15 to 24% of the value at 0 minutes.

When insulin and propranolol were given combined the half relaxation time failed to decrease (Fig. 3). On the contrary, a continuous increase of the half relaxation time to 476 msec. at 120 minutes, even higher than that seen during the glucose-

FIG. 1

FIG. 2

FIG. 3

FIG. 1.—Blood glucose and Achilles tendon reflex time during intravenous glucose-tolerance test in five adult subjects. FIG. 2.—Blood glucose and Achilles tendon reflex time during intravenous insulin-tolerance test in five adult subjects. FIG. 3.—Blood glucose and Achilles tendon reflex time during two intravenous insulin-tolerance tests in the same subject. — Insulin alone. ---- Insulin and propranolol.

tolerance test, was observed in spite of a markedly prolonged hypoglycaemia.

COMMENT

In all five subjects studied the mean half relaxation time increased after intravenous glucose administration and decreased after intravenous insulin administration. The increase during the glucose-tolerance test was slow and lagged considerably behind the peak of blood glucose concentration, while the decrease during the insulin-tolerance test was fast and coincided with the drop in blood glucose. This difference in the time relation between blood glucose concentration and half relaxation time in the two tests makes a direct effect of blood glucose on the half relaxation time unlikely. There seems more likely to be an indirect effect, mediated perhaps through a carbohydrate-regulating hormone like adrenaline, growth hormone, or cortisol. The absence of a decrease of the half relaxation time after simultaneous administration of insulin and propranolol suggests that the changes of blood glucose influence the half relaxation time by intermediary of the adrenaline system.

Whether the changes of the Achilles tendon reflexogram in thyroid disorders and in diabetes mellitus are related to the adrenaline system requires further investigation.

SUMMARY

In five normal subjects the Achilles tendon reflex time was prolonged by intravenous glucose and shortened by intravenous insulin administration. The effect of insulin was abolished when it was given after the application of propranolol.

Medical Memoranda

Foot-and-mouth Disease in Man

Brit. med. J., 1967, 4, 529-530

Though there are numerous reports in the literature of foot-and-mouth disease in man, the total number of possible cases is still very small in relation to the frequent exposure of farmers and others to the disease in parts of the world where infection is widespread in the livestock population (Platt, 1958). In many of the reported cases the criteria on which diagnosis was based were rather less than adequate, but Pilz and Garbe (1965) described a number of cases in which the diagnosis was more completely substantiated. The virus was recovered from vesicular lesions at high titre, and significant antibody titres were developed against the strain of virus isolated from the lesions. Material from suspected cases of foot-and-mouth disease in man has been submitted to the Animal Virus Research Institute at Pirbright on several occasions, but in none of these have we been successful in isolating virus or demonstrating specific antibodies. There is, however, little doubt that the patient whose case is described below became infected with foot-and-mouth disease virus.

CASE REPORT

The patient, a man aged 35, lived on a farm with his brother, but had only indirect contact with the livestock. An outbreak of foot-and-mouth disease developed on this farm on 22 July 1966, and one of the affected animals was a cow which supplied milk used in the farmhouse. The animals were slaughtered on 24 July, and though the patient watched this operation he took no part in it.

On 28 July he complained of a slight sore throat, which became worse on the 29th. On the 30th he had a temperature of 99° F. (37.2° C.), an inflamed throat, and a few blisters on the palms and dorsa of both hands. On 31 July his temperature was normal, but the blisters on his hands had increased in number. There were two further blisters between his toes and five or six weals on the side and front of his tongue. The blisters on the backs of his hands were about 2 mm. in diameter, while those on the palmar surface were between 5 mm. and 2 cm. in diameter. The weals on the tongue were solid swellings similar in size to the blisters on the palms. There were no swellings on the fauces, soft palate, cheeks, or gums. The patient described his lesions as uncomfortable and tingling, while the tongue was hot, tingling, and sore.

Epithelium was collected from one of the blisters on the back of the hand and transferred to a container with glycerin-phosphate

buffer. Two drops of fluid from another blister were added to this medium. Foot-and-mouth disease virus of type O was recovered from this material.

These lesions had regressed by 7 August, but further crops of blisters developed on the hands on 8 and 11 August and again in December. No virus was recovered from these lesions either at the Animal Virus Research Institute or at the Pathology Department of the Newcastle General Hospital. A series of blood samples were collected for antibody assay. As there was a possibility that the patient might still be a carrier of virus, throat swabs were collected at intervals and tested at both laboratories for the presence of virus. All were negative.

The patient was examined in March 1967 and again in April at the skin clinic of the Royal Victoria Hospital in Newcastle upon Tyne. The clinical syndrome was believed to be that of erythrasma and tinea pedis with a recurrent erythema multiforme. The second report stated that the hand lesions were suggestive of healing pompholyx, while some superficial erosions of the hard palate were thought to be aphthous ulcers.

LABORATORY EXAMINATION

Virus Isolation.—A suspension of epithelium collected on 31 July 1966 was inoculated into roller tube cultures of bovine thyroid cells (Snowdon, 1966). After 48 hours cytopathic change was seen and the culture fluid gave a positive reaction in the complement-fixation test with foot-and-mouth disease type O antiserum. Five days later a fresh suspension of the same epithelium was titrated in the same culture system. The epithelium was shown to contain $10^{6.4}$ TCD₅₀ virus per gramme. Further epithelial samples collected on 8 and 11 August were examined, but no virus was detected. Throat swabs collected on 4 August, 21 October, and 4, 10, and 18 November also gave no evidence of virus.

Serology.—Antibody titres obtained with foot-and-mouth disease antigens are shown in the Table. Sera were collected from five veterinary officers who had been in contact with infected cattle in Northumberland and from 12 members of the staff of the Animal Virus Research Institute, all of whom had come into contact with

Antibody Titres Obtained with Foot-and-mouth Disease Antigens

Serum Samples (Days After Infection)	Neutralizing Titre. Virus Type			C.F. Titre (Overnight Fixation)
	O	A	C	
5	1/178	<1/8	<1/8	≤16
30	1/708	<1/8	<1/8	36
40	1/355	<1/8	<1/8	54
120	1/256	<1/8	<1/8	24
154	1/80	<1/8	<1/8	Not tested

the virus of foot-and-mouth disease in the course of their normal work. All samples, tested in parallel with the serum from the patient, were negative (titre less than 1/8) except for one serum from a member of staff which showed a neutralizing titre of 1/22 against virus of type O.

DISCUSSION

It would appear that the patient had in fact contracted an infection by the virus of foot-and-mouth disease. The lesions observed, the high titre of virus recovered from the epithelium, and the rise in antibody titre all indicate the strong probability that he became infected with foot-and-mouth disease between 24 and 31 July 1966. The high initial antibody titre was probably due to the fact that the serum was collected at least five days after the illness was first noted by the patient. The decline in antibody titre at 120 and 154 days from the beginning of the illness agrees well with the observations of Pilz and Garbe (1965).

The absence of any antibody rise in association with the recrudescence of epithelial lesions indicates that these episodes are unlikely to have anything to do with foot-and-mouth disease. But the fact that the cause of the skin condition observed in these episodes, and possibly even in the first, remains undiagnosed suggests that epithelial damage of this nature might have raised the patient's susceptibility to the foot-and-mouth disease virus. His contact with infection was less than that of many people working with infected animals in Northumberland at that time, and it is known that epithelial

damage does increase the tendency to the development of lesions in experimental animals, possibly by increasing the phagocytosis of virus by epithelial cells.

The clinical signs shown in the initial illness accord with the appearance of foot-and-mouth disease in susceptible species, though the patient may also have been suffering from a skin condition of unknown origin. No spread to other humans appears to have occurred in this case, and, as the patient did not come into contact with animals either before or after his illness, there is no evidence of spread in this direction. There is, however, a clear case for restriction of movement of a suspected case in an agricultural area and for the treatment of the condition in isolation. Virus was recovered from only one of the samples—that obtained from the patient three days after the initial clinical signs. Throat swabs collected 7, 84, 98, and 106 days after infection were negative, as were epithelial samples taken at 11 and 14 days. It is therefore likely that the disease in man is relatively short-lived and that the period of infectivity is quite restricted.

Recurrent Tetanus

Brit. med. J., 1967, 4, 530

The incidence of tetanus reaches endemic proportions in Ceylon. A minimum of one case a week is admitted to any large hospital in the island. However, there is no record of a recurrence or of relapse. The following report is of a patient who had two attacks of unmistakable tetanus within three months of each other.

CASE REPORT

An 8-year-old Sinhalese girl was admitted to hospital on 23 February 1965 with a history of difficulty in opening her mouth and repeated "convulsions" of one day's duration. She also complained of pain in the abdominal wall and severe headache. There was a history of an injury to the left lower limb, nearly a month previously, for which she was treated in the outpatient department. Immunization against tetanus had not been carried out at the time.

On examination she was found to have trismus, risus sardonicus, and rigidity of all four limbs. No spasms were observed. She was afebrile. She had been treated with pethidine 25 mg. intramuscularly on admission, and chlorpromazine 25 mg. by mouth twice a day. Crystalline penicillin 300,000 units twice daily was given by intramuscular injection. Antitetanus serum was given in an initial dose of 100,000 units intravenously, followed by 100,000 units intramuscularly. The latter was repeated daily for six days.

The patient was well enough to be discharged from hospital in 23 days from the date of admission. No active immunization had been carried out at the time. She was quite well after discharge and attended school until 30 May 1965.

On 3 June she was readmitted to hospital with trismus of four days' duration, and "convulsions" for one day. On examination she had severe trismus and a well-marked risus sardonicus. Neck stiffness was very conspicuous. No spasms were observed. She was treated with pethidine 50 mg. and chlorpromazine 50 mg. intra-

muscularly six-hourly. This dosage was progressively reduced and "tailed off."

Crystalline penicillin 500,000 units intramuscularly twice daily was started, but had to be stopped on the third day, as she complained of severe itching of the body and developed an urticarial rash in both axillae. Oral tetracycline 250 mg. six-hourly was substituted. Calcium gluconate 5 ml. intravenously was given daily. An intradermal test for sensitivity to antitetanus serum was strongly positive. A weal 4.2 by 2.2 cm. developed after the diluted serum (0.1 ml.) was introduced into an area of 1 sq. cm. Thus we were unwilling to administer serum even in fractional doses. The hospital had run out of toxoid at the time, so this could not be given.

Recovery was uneventful. No spasms were noted at any time. The patient was discharged on 27 June, and was quite well except for some residual trismus. It should be noted that there was no fresh trauma to cause or provoke this second attack of tetanus.

COMMENT

Standard textbooks of surgery make no mention of cases of recurrent or relapsing tetanus. However, it is stated that there is no immunity conferred on a patient after an attack of tetanus. This must be so, because there are no fewer than eight antigenic strains of *Clostridium tetani* and also because neither the bacillus nor its spores are said to enter the blood stream or be carried to distant sites. Any immunity, active or passive, will be to the exotoxin, which is actively antigenic.

This case illustrates the necessity for active immunization against tetanus after an attack of the disease. This could be done with adsorbed toxoid, three 1-ml. doses at intervals of three to six weeks. A booster dose of 1 ml. of toxoid after an injury likely to produce tetanus would suffice, and is recommended.

Hip Arthroplasty in a Haemophiliac and Subsequent Prophylactic Therapy with Cryoprecipitate

Brit. med. J., 1967, 4, 531-532

Operations on haemophiliacs are becoming increasingly common, and with the provision of antihaemophilic globulin concentrates much safer. Reports of the use of cryoprecipitate in controlling haemophilic bleeding suggest that this is a most effective form of replacement therapy (Pool and Shannon, 1965; Bennett *et al.*, 1967; Brown *et al.*, 1967). The purpose of this paper is to report the performance of a successful hip arthroplasty in a young severe haemophiliac who sustained a fracture of the left femoral neck which failed to unite. This operation is believed to be the first of its kind performed on a haemophiliac, and may provide grounds for optimism in the treatment of other patients in a similar situation. Furthermore, it has been possible to organize successful prophylactic therapy.

CASE REPORT

A 21-year-old haemophiliac had sustained repeated haemorrhagic episodes since he was 3 years old. There was no family history of haemophilia, but repeated antihaemophilic globulin assays (Hardisty and Ingram, 1965) had shown concentrations of less than 1% in his plasma. In the previous three years he had had repeated haemorrhages, many of which had been into joints, and these episodes had necessitated his admission to hospital nine times.

In October 1966 he fell and sustained an acute haemarthrosis of his left hip, and x-ray examination showed a transverse fracture of the left femoral neck. The acute episode subsided after transfusion of 6 units of cryoprecipitate and the hip fracture was treated by traction, which was maintained for 16 weeks. X-ray films after this time showed that union had not taken place.

Treatment and progress during and after operation.

The decision to insert a prosthesis in such a young man was made with difficulty, but it was judged the best treatment because his left hip was one of his few normal joints and it was felt necessary to make this painless, stable, and mobile.

Supplies of cryoprecipitate were arranged through the co-operation of the North London Blood Transfusion Centre, and were prepared according to a modification of the method of Pool and Shannon (1965) (Bennett *et al.*, 1967).

An initial loading dose of 20 units was administered, resulting in an antihaemophilic globulin level of 120% and a cephalin kaolin clotting-time of 56 seconds. The left hip was exposed through the posterior approach. The capsule was opened and adhesions on the joint were marked. There was a loose pseudarthrosis with no suggestion of union. The head of the femur was removed, the neck trimmed, the medullary cavity reamed, and a Thompson prosthesis inserted and fixed with Surgical Simplex P. The hip was reduced and the wound closed in layers. The operation lasted one hour; there was no undue haemorrhage, and no blood transfusion was required.

Four hours after the operation antihaemophilic globulin levels had fallen to 40% and further replacement was required. Subsequent replacements of antihaemophilic globulin were given at 12-hourly intervals, the dose varying according to the antihaemophilic globulin levels obtained, but 9 units twice daily produced satisfactory levels (see Chart), and this dosage was continued for eight weeks. The incision healed uneventfully, and after two weeks the patient was mobilized. Intensive physiotherapy was required, as there had been considerable muscle-wasting from immobilization, and the administration of cryoprecipitate was continued.

In view of the history of frequent severe bleeding over the three previous years it was decided to attempt to continue replacement therapy on a diminished scale by teaching the patient to give himself 6 units of cryoprecipitate on alternate days, on the assumption that this might result in his haemophilic state behaving as a mild rather than as a severe one. He soon learnt to administer his own intravenous injections and was able to continue this regimen, storing a week's supply of cryoprecipitate at home in a deep freeze. Antihaemophilic globulin levels of 15-20% were obtained immediately after the injection of 6 units of cryoprecipitate, the level falling to 1% in 48 hours before the next injection (see Table). On this regimen there has been no further bleeding, and the patient is

Antihæmophilic Globulin Levels after 6 Units of Cryoprecipitate

Time in hours	0	0.5	4	24	48
AHG levels (% of normal)	<1	14	8	2.5	<1

ambulant. On one occasion he had a severe fall and sustained only limited bruising; on another occasion he developed a mild haemarthrosis in his right knee after a severe jolt in a motor accident. Both these incidents resulted in much less incapacity than had been expected. Repeated antihaemophilic globulin assays on a number of occasions produced similar loading concentrations, and no clotting inhibitor or γ -globulin antibodies were detected. Treatment has continued for six months with these satisfactory results.

COMMENT

The control of bleeding in haemophilia by the administration of antihaemophilic globulin concentrates is a well-accepted procedure and various operations have been carried out under this cover. Cryoprecipitate appears to be an effective answer to haemophilia control by providing a high-potency source of human antihaemophilic globulin in small volumes of material, yet resulting in the unused red cells and plasma being retained for transfusion purposes.

In the case presented here bleeding has been controlled and a major hip operation performed under cover of this material. The results have been as good as had been hoped, and the patient has been mobilized without further bleeding. It has further been possible to teach him to administer his own cryoprecipitate intravenously, and from the intermittent administra-

tion of a relatively small dose on alternate days it would appear that the course of his disease has been reduced from one causing major to one causing minimal incapacity. How long it will be possible to continue replacement therapy in this way remains to be seen, but it may offer a useful means of tiding severe haemophiliacs over serious exacerbations of their disease. The risk of homologous serum jaundice would appear to be appreciable, but our patient had had so many previous administrations of plasma that it was thought likely that he had developed immunity. An additional risk of the production of antibody to antihaemophilic globulin or other globulins must be borne in mind. Those patients who possess trace amounts of antihaemophilic globulin and who presumably do not suffer from a complete gene deletion would seem unlikely to develop antihaemophilic globulin antibodies, and so far no γ -globulin antibodies have been detected in our patient. If prolonged treatment

of haemophilia in this way is practicable, more adequate provision of cryoprecipitate on a national scale will be required.

Delayed Perforation of Large Bowel Due to Unusual Ingested Foreign Body

Brit. med. J., 1967, 4, 532

A blunt ingested foreign body usually does not give rise to any trouble once it has negotiated the ileocaecal junction. In the present case, obstruction and later perforation of the colon resulted from massive impaction of cloth fabric.

CASE REPORT

A 29-year-old woman was admitted as an emergency case because of a five-day history of lower abdominal colicky pain, vomiting, and constipation. Early laparotomy seemed indicated because of a firm tender mass in the pouch of Douglas which was thought to be a twisted ovarian cyst.

Operative Findings.—Some clear serous fluid was found in the peritoneal cavity, but the ovaries were normal. The whole of the large bowel was loaded down to almost the rectosigmoid junction. The rectum and the distal few inches of the sigmoid colon were empty and appeared normal to inspection and palpation. The distension was maximal in the pelvic colon, which was congested, thickened, and oedematous. It was angry-looking and the appearance was not unlike that of Crohn's disease. However, the mesentery and its lymph nodes were not involved. There was an area of necrosis measuring about 3 mm. in diameter in the wall of the pelvic colon, situated between the mesenteric border and the anterior taenia coli. This was of paper-like thickness, was light green in colour, and was covered with purulent exudate. The adjacent appendices epiploicae were also involved by this acute inflammatory process. There was no evidence of any diverticulosis or diverticu-

litis. As perforation seemed imminent, the loop of pelvic colon was exteriorized after milking down its contents.

The diagnosis of this strange lesion was made on the fourth postoperative day, when the milked-down contents were passed per rectum. These consisted of several portions of cloth fabric, mostly derived from vests, stockings, and pyjamas (see illustration). On the ninth postoperative day the exteriorized pelvic colon was opened as the patient had become acutely obstructed. After this many yards of fabric, mainly in lengths of about 15 cm., were removed from the colon.

On the thirteenth postoperative day she developed faecal peritonitis after perforation of the descending colon due to impacted fabric, and a transverse colostomy was performed. Her convalescence was stormy and prolonged, but eventually she left hospital after closure of the two colostomies.

COMMENT

Only two cases of perforation of the large bowel due to blunt foreign bodies have been reported in the medical literature. In the case reported by Williamson (1952) it was the result of a gall-stone impaction, while in Goatcher's (1953) case the cause was similar to the present one.

Ward-McQuaid (1950) studied the various types of ingested foodstuffs which could cause intestinal obstruction but rarely perforation and found that the terminal ileum was the commonest site of impaction.

The above case becomes interesting from various points of view: (1) On routine examination of the patient one would not have thought of any mental retardation. She was happily married and had two children. However, she was later seen by a psychiatrist, who found her to be mentally deficient. (2) The pathology of impending perforation has not been described previously; as in Goatcher's case, it was missed by prolonging the conservative treatment. The appearance can easily be confused with Crohn's disease, particularly if the impaction should take place in the terminal ileum. (3) Though the patient presented as a case of intestinal obstruction, a delayed perforation and faecal peritonitis could not be avoided as in Goatcher's case. To guard against such a complication should such a case be discovered at laparotomy it is advisable to perform a colostomy and milk out all the impacted material.

I wish to thank Mr. J. M. Moore for his guidance in the management of this case and useful suggestions in the preparation of the paper.

DISEASE OF THE DIGESTIVE SYSTEM

Carcinoma of the Stomach

J. L. DAWSON,* M.S., F.R.C.S.

Carcinoma of the stomach is a common disease, but despite all efforts at early diagnosis and the application of radical methods of treatment the overall five-year survival rate is low—probably somewhere between 5% and 10%.

Pathogenesis

The association between blood group A and cancer of the stomach is found throughout the world and represents a weak but significant genetic link. Occasionally a strong family history of carcinoma is encountered.

The incidence varies in different parts of the world, e.g., high in Japan, low in the United States. It varies in different parts of the same country; it is, for example, high in North Wales compared with the rest of the United Kingdom. These variations have been variously attributed to trace elements in the water or methods of food preparation and eating; and it is interesting to note that the Japanese migrants to the United States show a fall in incidence compared with the rate in Japan, which suggests that the environmental factors are probably the most important. This is further confirmed by the fact that the incidence of the disease is actually showing a decline in the past 30 years in the United States.

Predisposing Pathological Conditions

Pernicious Anaemia.—There is a greatly increased incidence of gastric carcinoma in this disease, about twenty times the expected. The carcinoma most frequently develops in the body of the stomach—where the mucosal atrophy is—whereas in the population at large carcinoma most often originates in the pyloric antrum.

Atrophic Gastritis and Achlorhydria.—This condition almost certainly predisposes to the development of carcinoma. It is much more commonly found in association with carcinoma than with gastric ulcer or duodenal ulcer; the carcinoma is usually surrounded by atrophic mucosa, often with areas of intestinal metaplasia, which is frequent in atrophic gastritis. Atrophic gastritis is most often found in the antrum—the commonest site for carcinoma. Gastric polyps, although rare, show intestinal metaplasia and may be the origin of carcinoma.¹

Benign Gastric Ulcer.—Malignant change in a gastric ulcer almost certainly does occur. Applying strict pathological criteria for the diagnosis of ulcer cancer the incidence is probably about 10% in those stomachs resected. Much more often an error in clinical diagnosis is made—the carcinoma is wrongly regarded as a benign ulcer.

Pathology

Approximately a half of all gastric carcinomata occur at the pyloric end of the stomach. They have a variable macroscopic appearance (Borrmann): (1) *Polypoid*—growing into the lumen surrounded by atrophic mucosa. (2) *Ulcerating*—which penetrates deeply and has a raised edge well differentiated from the surrounding mucosa. (3) *Ulcerating and infiltrating*—the edge of the ulcer merges into the surrounding mucosa with obvious infiltration. (4) *Infiltrating*—in which no clear transition from normal to abnormal is seen macroscopically. The whole stomach may be involved. If ulceration develops it may be shallow or deep. It is this variety which gives rise to linitis plastica. Multiple centres of origin are often seen.

Histological appearances of carcinoma of the stomach may be graded according to the degree of cell differentiation from 1-4 (Broders).

Spread occurs by direct extension through the stomach wall and often involves adjacent viscera. Lymphatic spread is frequently present and involves the regional nodes along the lesser curvature, in the greater omentum, the hilum of the spleen, the subpyloric and suprapancreatic glands. The site of the tumour usually determines the nodes first involved. Blood spread and transcoelomic spread are also frequent.

Superficial Cancer

In this variety the carcinoma is found to involve only the mucosa of the stomach and does not penetrate in the muscularis mucosa, though spread to the regional lymph nodes may have occurred. This type of growth may be impossible to feel from outside the stomach²; it is usually well differentiated. Whether many stomach cancers begin in this way or whether it represents a form in which host resistance is high is not yet settled. The latter possibility seems likely, for even with nodal involvement the five-year survival rate is very high³ after resection (75%).

Symptoms

The oft-quoted clinical syndrome of epigastric pain, anorexia, and loss of weight associated with an epigastric mass represents advanced disease. Diagnosis at this stage will not usually benefit the patient very much apart from palliation of symptoms.

Several investigators have found that the average delay between the onset of symptoms and definitive treatment varies from six months to a year.⁴ The patient does not usually seek advice until symptoms have been present for at least six months. The first symptoms noted are firstly a slight diminution of appetite with a distaste for some foods and a relish for others,

* Consultant Surgeon, King's College Hospital, London, and Bromley Hospital, Kent.

and secondly vague epigastric discomfort—usually a feeling of fullness after meals, sometimes associated with belching. The patient often adjusts his diet with temporary relief of symptoms for weeks or even months.

Lesions close to the pylorus or cardia will produce obstructive symptoms (vomiting or dysphagia) comparatively early. Occasionally haematemesis and melaena or perforation will be the presenting symptom. Unexplained iron deficiency anaemia due to occult bleeding will sometimes lead to the discovery of a completely symptomless tumour. Rarely diarrhoea will be the presenting symptom, usually in the linitis plastica type of lesion. All too often, however, it is the manifestations of metastatic disease which cause the patient to seek advice: ascites, gross loss of weight, jaundice, and loss of strength.

Clinical Examination and Investigation

Physical examination is directed towards detection of anaemia, palpable supraclavicular nodes, and evidence of loss of weight. Examination of the abdomen may reveal a palpable mass, an enlarged liver, or the presence of ascites. Pelvic deposits may be palpable on rectal examination.

Barium studies are the most useful special investigations and they achieve a high degree of accuracy in good hands. The signs vary with the site and type of cancer—for example, deep ulceration, filling defect, areas of mucosal irregularity, or rigidity of the stomach wall. An x-ray film of the chest should be done to exclude metastatic disease.

Most gastric carcinomata are easily seen at gastroscopy and the diagnosis is not in doubt. Sometimes it is not possible to distinguish between a benign and malignant ulcer. If the lesion shows no evidence of healing when re-examined after the patient has rested in bed for 14 to 21 days then it should be regarded as malignant and explored.

Gastroscope examination has become available in the past few years.⁵ The instrument is flexible, so that the discomfort for the patient is comparable with gastroscopy using the fibroscope. The gastroscope has a great advantage over the gastro-scope in that it provides a permanent record of the appearances of the gastric mucosa for comparison with later examinations. It is also much easier to learn the technique and interpretation of appearances with a permanent record available. The accuracy of the methods varies from one reported series to another, but in Japan, where the method originated, the gastroscope has been found with experience to be slightly more accurate than even barium studies. It should be of special value in diagnosing superficial carcinoma of the stomach.

Achlorhydria is frequently found with carcinoma (excluding those patients with pernicious anaemia) but some 25% of patients will have normal gastric secretion, so that studies of secretion are not of much value in the diagnosis of a particular patient. Patients found to be achlorhydric may be screened as a high risk group, as it has been estimated that the risk of gastric cancer is 4.5 times higher than normal.¹

Gastric cytology (including tetracycline staining) and the use of radioactive phosphorus have also been employed, but they are time-consuming and are not widely used. Sometimes cytology will lead to a correct diagnosis of carcinoma when the other methods have not.⁶

Treatment

The only treatment producing a significant number of long-term survivors is excision of the tumour and adjacent stomach. In a large series reported from the Mayo Clinic it has been noted that in the past decade the proportions of patients who were explored, resected, and the number surviving five years have all risen. No proper controlled series is available, but these results have been attributed to the increased use of radical

surgery. Most of the patients treated at the Mayo Clinic come from afar, so that some selection may be exercised by the referring doctor. It is therefore not possible to say definitely whether these improved figures are real or apparent.

In the light of present knowledge radical surgery should be undertaken if the tumour is macroscopically limited to the stomach. The growth, with 5 cm. of macroscopically normal stomach either side, should be resected together with the regional lymph nodes.⁶

For lesions in the distal part of the stomach these criteria are satisfied by a radical lower partial gastrectomy, done through the abdomen. The distal stomach and the first part of the duodenum are removed together with the greater omentum, the lesser omentum, the subpyloric nodes, and the nodes along the hepatic artery and coeliac axis. The left gastric artery is divided flush at the coeliac axis. If the posterior wall of the stomach is involved then the suprapancreatic nodes and the peritoneum of the lesser sac are removed. Continuity is restored by an antecolic gastrojejunal anastomosis.

For lesions of the proximal stomach a thoraco-abdominal approach is required, and, except for tumours limited to the cardia, a total gastrectomy is done, taking the spleen and suprapancreatic and coeliac nodes. If the tumour is on the posterior wall of the stomach, the tail and part of the body of the pancreas is often removed to achieve an *en bloc* resection.

For tumours limited to the cardia a radical upper partial gastrectomy may be done, retaining the distal half of the stomach, the lesser curve being closed and the oesophagus anastomosed to the greater curve side of the cut end of the stomach. The lymph nodes of the coeliac axis and suprapancreatic region are taken, together with the tissues around the hiatus, the spleen, and the adjacent parts of the greater omentum.

If the carcinoma is found to have spread beyond the limits of complete removal, then a more limited palliative resection should be done if the tumour is mobile, because resection usually produces better palliation than bypass procedures. If the tumour is irremovable and the patient has severe obstructive symptoms at either the distal or proximal end of the stomach, then gastroenterostomy or end-in-side jejuno-oesophagostomy will afford the best symptomatic relief.

In recent years systemic or regional chemotherapy has been used and may produce temporary remission of symptoms, although in most recorded series this is usually short-lived, a matter of a few weeks only.⁷

Prognosis

The outlook for the patient depends upon the length of the history, the extent of the lesion (including nodal involvement), and the degree of cell differentiation. Somewhat paradoxically it has been found that the longer the history the better the prognosis—this is probably best explained by the suggestion that the patient who takes many months before his symptoms progress to significance after first appearing has a much more slowly growing tumour than the patient whose symptoms demand investigation only a short period after first appearing.

The proliferative type of tumour usually carries the most favourable prognosis, while the linitis plastica type of lesion is almost never associated with five years' survival. The well-differentiated tumours carry a better prognosis than the anaplastic.

Infiltration of the nodes found on examination of the specimen removed at radical operation is usually an accurate guide to prognosis. Of those patients found to have involvement of the subpyloric glands only 6% survive five years; while if only the lesser curve nodes are involved 65% survive for five years.⁸

The prognosis of superficial carcinoma of the stomach is altogether different—95% survival in those without nodal involvement and 75% for those with nodal involvement.³

Prophylaxis

For the vast majority of patients it is difficult to see how the prognosis can be improved. The average delay between onset of symptoms and seeking advice is six months, so that the biology of the tumour usually determines the outcome.

Screening of high risk groups—for example, those with pernicious anaemia, will make little difference to the overall figures because only 5% of gastric carcinomas occur in these patients.

There is some evidence that earlier diagnosis would improve the outlook. When a large group of patients with pernicious anaemia was screened, 38 cancers were found; in 22 without symptoms only 6 had nodal metastases at surgery. On the other hand, of the remainder with mild to moderate symptoms elicited on questioning (the patients had not sought advice) 13 out of 15 had nodal deposits.⁹ In patients with pernicious anaemia, six-monthly x-ray examinations have been recom-

mended. Against the credit of picking up a cancer in less than 5% of patients must be set the introspection and neurosis engendered in the patient, the irradiation hazard, and the considerable demands on the time of a skilled radiologist.

TODAY'S DRUGS

With the help of expert contributors we publish below notes on a selection of drugs in current use.

Allantoin

This drug is marketed by Stafford-Miller Limited under the name of Alphosyl. Two preparations are available—a cream containing 5% of a refined alcoholic extract of crude coal tar and 2% allantoin in a vanishing cream base, or a greaseless, stainless lotion. It is a recent addition to the range of agents used in the treatment of psoriasis.

Chemistry and Pharmacology

The chemical structure of allantoin is:

5 Ureidohydantoin or glyoxyldureide

It has been shown that plant extracts containing large amounts of allantoin produced healing of intractable ulcers, as did pure solutions of allantoin. Similarly, the successful use of maggots in the treatment of chronic ulcers and non-healing wounds is also apparently due to allantoin present in the excretions of the maggots. Though it might seem that this action would not have any direct application in the treatment of psoriasis, allantoin has been shown to possess a keratin-dispersing activity, which may explain its beneficial activity in psoriasis.

Clinical Use

Trials in the United States of America have shown^{1,2} that allantoin appears of value in the management of psoriasis. From 70% to 88% of patients were helped, and 50% or more had their lesions cleared completely by the treatment. Clearing tended to be slow and treatment had to be main-

tained for relatively long periods of time, while any recurrence had to be treated immediately. Nevertheless, these studies were not well controlled, even after allowance has been made for the difficulties in conducting satisfactory clinical trials of treatment in psoriasis.

It is also suggested that allantoin is of value in the treatment of chronic scaling dermatoses other than psoriasis, but not enough has been written about its use in such conditions to enable any assessment to be made.

Advantages

Allantoin has not been reported as causing any skin reactions and phototoxicity has not been observed. The preparations are acceptable to the patients. The cream can be applied under polyethylene occlusion with increased effect.

It seems that allantoin may well be of value in the management of psoriasis. It certainly avoids the hazards of anti-metabolites and local and systemic corticosteroids, and it does not have the disadvantages of staining, burning, and discoloration that occur with other topical preparations.

Presentation and Cost

Alphosyl is available as a 5% refined alcoholic extract of coal tar and 2% allantoin in a cream and lotion.

The basic N.H.S. price of 60 g. of cream is 9s. 2d. and of 8 fluid oz. lotion 17s. 7d.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Killed-measles-virus Vaccine

Q.—In view of a report¹ that some children who had been immunized with killed-measles-virus vaccine developed a severe atypical form of the disease when exposed to natural infection, and of the opinion that the administration of killed vaccine alters the host in some unknown way, would it be wise for the time to refrain from using killed-measles-virus vaccine?

A.—In the studies reported by Fulginiti and Kempe,¹ in which an "atypical measles" developed in children five to six years after giving killed measles vaccine, two groups were involved. In one three doses of killed vaccine were given (KKK), while in the other two doses of killed vaccine preceded a single dose of live vaccine (KKL). In Britain either live vaccine alone has been used—that has not given rise to this atypical measles—or a single dose of killed vaccine followed by the live vaccine, which was not a schedule studied by Fulginiti and Kempe.

In the Medical Research Council trials a few of the children in each of the vaccinated groups have had measles, but none has had this atypical measles. It is perhaps significant, however, that so far the observation period has been only three years, whereas the cases in America occurred five to six years after primary immunization.

It is generally believed that the killed vaccine in the schedules KKK or KKL has sensitized the vaccinees rather than immunizing them, and it is known that immunity has fallen within a year. In view of the fact that the immunity to both the KL and the L alone schedules used in Britain seem to be holding up for at least three years, it is hopeful that satisfactory immunity has been conferred and that cases of atypical measles will not be seen. There has been no evidence from the M.R.C. trials, therefore, that a KL schedule for those demanding reaction-free immunization should be stopped.

Scriver's Test for Phenylketonuria

Q.—What is Scriver's test for phenylketonuria? How do the results of this test compare with the Phenistix test?

A.—The term "Scriver's test" is somewhat misleading. In 1964 Scriver, Davies, and Cullen¹ described a simple method for screening for amino-acid disorders. This is a semi-quantitative technique of one-dimensional chromatography applied to the plasma, for which blood is taken by heel-prick and run into heparinized capillary tubes. The tubes are then sealed with Plasticine. They can be sent through the post in suitable containers. The method can be easily adapted for mass screening.

The advantages compared to the Phenistix test are that: (1) it is easier to obtain a small

sample of blood from an infant than a fresh specimen of urine; (2) other disorders of amino-acid metabolism as well as phenylketonuria can be detected; (3) it can be used as a rough method of control during the dietary treatment of phenylketonuria; and (4) a standardized method can be applied to all specimens.

Some of the shortcomings of the Phenistix test have been recently described by Stephenson and McBean,² and Woolf³ has briefly reviewed the present situation.

Thalidomide in Leprosy

Q.—Has thalidomide proved effective in the treatment of leprosy?

A.—Patients with lepromatous-type leprosy frequently develop serious reactions—variably referred to as lepra reactions, lepromatous exacerbations, or erythema nodosum leprosum (E.N.L.)—during the course of anti-leprosy treatment. These reactions are commonly manifested by outbreaks of subcutaneous nodules; pain in bones, joints, and nerves; and fever. They may be fatal. When these reactions occur under field conditions chemotherapy is usually stopped, and the more severe reactions can be controlled only by prolonged treatment with corticosteroids, resulting in the usual toxic side-effects.

There is now good evidence that thalidomide can control lepra reactions of this type as effectively as corticosteroids. This finding arose from a chance observation by Sheskin,¹ in Israel, while using thalidomide as a sedative for patients with lepra reactions. His first observation was based on six patients,¹ his second on 13 patients in Israel,² and more recently on those in an extensive double-blind trial carried out in Venezuela.³ The trial comprised 173 treatments, in which thalidomide was used in 85 and a placebo in 88. In the thalidomide-treated cases there was amelioration in 92% and no change in 8%; no deterioration was observed. In the placebo-treated cases amelioration was observed in 27%, no change in 50%, and a deterioration in 23%. Similar satisfactory results have been obtained by Cazort and his colleagues⁴ in 24 patients treated with thalidomide in Thailand.

Treatment has been initiated with 100 mg. thalidomide thrice daily, and the reactions have shown improvement within 48 hours. In some of Sheskin's cases treatment has been maintained successfully for 10 months and the dose of thalidomide reduced to 100 mg. a day. In the majority of patients thalidomide has enabled the patients to be weaned of corticosteroids. The complications have been dryness of the mouth, constipation, and various skin eruptions, but none were severe enough to necessitate withdrawal of treatment. Even with prolonged treatment the compli-

cations were considered to be less serious than those produced by corticosteroids. Because of the teratogenic action of thalidomide the drug was used only in male patients or female patients beyond child-bearing age.

Therefore, despite the promising results obtained with thalidomide in the control of lepra reactions, and particularly as an alternative to corticosteroids, its use can be envisaged only at centres where the patients are under rigorous supervision. There is now good evidence that thalidomide has an immunosuppressant action in animals, as demonstrated in the skin homograft reaction.⁵ However, the observation that it depresses reactional phases in patients with leprosy provides the first direct evidence that thalidomide can be also an immunosuppressive in man.

Notes and Comments

Medical Equipment for Explorers.—Dr. L. M. KELLY (Board of Trade, London S.E.1) writes: This question ("Any Questions?" 7 October, p. 43) concerning the kind of medical equipment which might be taken by laymen for a three-month voyage in a sailing-boat also raised the question of a suitable medical book. I should like to draw attention to the latest edition of the *Ship Captain's Medical Guide*.¹ This medical guide was devised for use on board ships which do not carry a doctor and is written especially for use by laymen. It might be considered of value to explorers, to those on expeditions in remote areas, or indeed to any isolated community where no doctor is at hand.

REFERENCE

- ¹ *Ship Captain's Medical Guide*, 1967. H.M.S.O., London.

Oral Diuretics and Hyperuricaemia.—Professor W. I. CRANSTON (Department of Medicine, St. Thomas's Hospital, London S.E.1) writes: In answer to this question ("Any Questions?" 28 October, p. 221) it is stated that triamterene does not cause elevation of uric acid. I do not believe this to be true. The evidence for this belief is given in a paper by myself and colleagues.¹ There is also indirect evidence in a paper by Heath and Freis.² I do not think this is of any particular importance with regard to the question which was raised, and I mention it only in the interests of accuracy.

OUR EXPERT replies: I am grateful to Professor Cranston for drawing my attention to the fact that there is evidence that triamterene, like the other oral diuretics, probably does cause a rise in serum uric acid. It would appear from the two references he gives that the degree of hyperuricaemia with triamterene is less than that produced by equivalent doses of other oral diuretics. As he says, the matter is relatively unimportant in relation to the question which was asked.

Book Reviews

Being a Good G.P.

The Doctor-Patient Relationship. By Kevin Browne, M.B., B.S., D.Obst.R.C.O.G., D.C.H., and Paul Freeling, M.B., B.S. (Pp. 73+vii. 10s. 6d.) Edinburgh and London: E. & S. Livingstone. 1967.

A characteristic of many books and articles written for general practitioners is the tendency of their authors to equate the function and requirements of general practitioners with those of hospital junior doctors. This is a basic misconception which the authors of *The Doctor-Patient Relationship* avoid. Their thesis is that the role of the general practitioner is unique and that particular training and skills are necessary for him to fulfil satisfactorily his primary role of "first contact doctor."

They consider it important for the general practitioner to learn to use as a diagnostic and therapeutic agent the emotional responses evoked in him by the attitude and bearing of his patients. This emotional response between the doctor and his patient is in their opinion much less important, diagnostically and therapeutically, for the specialist than for the general practitioner. Their purpose is to show some of the ways in which an understanding of the emotional transaction occur-

ring between a doctor and his patient can be used therapeutically. While acknowledging the importance of experience, they suggest that the necessary basic insight is best obtained by a period of formal training, and mention briefly two contrasting training schemes. One scheme they mention is the general practitioner seminars at the Tavistock Clinic, and one wonders to what extent these seminars may have helped to formulate some of the concepts expressed in their book.

Browne and Freeling write clearly and well. Their skill in handling the emotional problems of their patients is evident from the many case reports with which they illustrate their comments. Their book contains much that is interesting and admirable, but little that is fundamentally new. Nevertheless, most practitioners could learn from it, and I must record success with two patients after using one of their techniques. They describe various ways in which a doctor's emotional response—be it anger, depression, sexuality,

anxiety, or sympathy—when properly recognized and understood can be used to help the patient. The important role of relatives and colleagues in precipitating or affecting an illness is indicated. The need for the doctor to be constantly alert is underlined and the habit of some patients to report their main anxieties as they disappear through the surgery door is noted. The small extent to which they record using psychotropic drugs is noteworthy, especially, I felt, as I might have treated some of their depressed patients with a thymoleptic drug.

This book was originally published as a series of thirteen articles in *The Practitioner*. The chapters are short and divided into subsections that are almost complete entities in themselves. The contents and structure are such that it can be browsed through at leisure. New entrants will find it a useful introduction to an important aspect of general practice. Older practitioners may well feel that they have learnt from experience much of what is implicit in it; if not, they now have an excellent opportunity to learn from the experience of others.

Proteins and Related Subjects

Protides of the Biological Fluids. Proceedings of the 14th Colloquium, Bruges, 1966. Edited by H. Peeters. (Pp. 734+xiii; illustrated. £12.) London: Elsevier. 1967.

A notable annual event in biochemistry is the meeting on proteins and related subjects in Bruges, steered by Professor H. Peeters, who has now edited the proceedings of the 1966 colloquium. Printed in small but readable type on some 700 pages, there are more than 100 contributions. The authors' index consists of almost twice as many names, and the subject index lists some 500 items. It is clear that it is not possible to do such a book full justice in a review. In addition there must have been in the course of this meeting many informal exchanges which must have added to the delight and inspiration of this colloquium, and which could not find their way into print.

The volume is introduced by an academic lecture given by Professor E. F. Lüscher, of Berne, on the biochemical properties and biological function of fibrinogen. Although Professor Lüscher himself describes his contribution as a "brief account," it is in fact an exhaustive survey of the subject, discussing the known properties of the fibrinogen molecule and its biological functions and the areas where future research is required. This lecture alone is supported by 139 references.

There are four main sections. The first deals with metal-binding proteins, and the subsection concerned with the structure and function of these compounds includes such attractive features as pictures of molecular

structures and a complete table of metallo-protein enzymes, their function and distribution. The metals include magnesium, manganese, cobalt, zinc, iron, copper, and even molybdenum, and the enzymes amount now to more than 40. One subsection is entirely devoted to the iron binding of transferrin, lactoferrin, and ferredoxin, and other subsections to the copper binding of ceruloplasmin, and to proteins binding zinc, manganese, and vanadium, respectively.

The second major section deals with protein levels and protein turnover. Methods are described such as the use of computers to analyse the metabolism of tissue proteins. Regulation factors are discussed such as the relation between synthesis, metabolism, and serum concentration of plasma proteins, and the synthesis of proteins in cultures of human lymphocytes. One subsection is concerned with individual plasma proteins such as albumin, gammaglobulin, haptoglobin, and lipoprotein.

The third section is devoted to the determination of protein structure by physical methods, and, among others, includes a lucid account of the optical rotatory dispersion of α helical and β structures in relation to protein conformation. There is also a contribution in which the application of this technique to the investigation of Bence Jones proteins is discussed in detail. The fourth section includes numerous papers on separation techniques, improvements of chromatography by recycling to cause zone sharpening, new light on D.E.A.E. cellulose and D.E.A.E. Sephadex, variations in immuno-electrophoresis, and gel infiltration. Gel filtration can now also be used with considerable accuracy for the determination of molecular weight. A

fifth section includes various papers such as a contribution on the isoenzymes of catalase amongst the soluble non-haemoglobin proteins of red cells.

As usual for the proceedings of the Bruges conferences, this volume will be a rich source of up-to-date information for a wide circle of research workers interested in proteins of biological fluids.

H. LEHMANN.

Cancer Methodology

Methods of Cancer Research. Vol. 1. Edited by Harris Busch. (Pp. 612+xvi; illustrated. £11 4s.) New York and London: Academic Press. 1967.

This is the first of four volumes intended "for young individuals entering the field of cancer research." In fact many graduate students and postdoctoral fellows may be working for a long time on cancer problems without the intention of dedicating their scientific lives to cancer research. They may therefore hesitate to embark on equipping themselves with a comprehensive knowledge of techniques applicable to the field. Later, when they feel committed to cancer research, they may well have only limited time for wide and general reading. The present series may therefore be doing itself less than justice by restricting its appeal to workers in the cancer field. In any case many of the chapters are of interest in related biological and medical areas.

The first volume consists of ten review articles, each of them between 20 and 100 pages. Some of them might just as well have

appeared in the *Advances in Cancer Research* series produced by the same publishers. The volume begins with a chapter by Etienne de Harven, on methods in electromicroscopic cytology. Like others in the book, this contribution is lucid and informative; nevertheless, the serious student of electronmicroscopy would need to consult longer textbooks. This is more obvious in the case of M. B. Shimkin's chapter on epidemiology, which is merely a brief statement of the problem rather than a description of methods. A happier balance is achieved by J. H. and E. K. Weisburger in their chapter on tests for chemical carcinogens. Here much useful information of a practical nature is given in a sufficiently broadly based way to maintain the interest of the general reader. It is a pity that the chapter by T. S. Hsu and F. E. Arrighi was limited to karyological methods and did not extend over the whole field of cytogenetics. Also it is surprising that in a book on cancer methodology there are no illustrations of tumour karyotypes. Instead there appear the seemingly irrelevant pictures of the karyotypes of a male bobcat and of a male ocelot. A more serious omission is of any reference to the quantitative assessment of chromosome size and D.N.A. content by microspectrophotometry or of chromosome mass by interference microscopy.

The standards of writing, of presentation, and of editing are high, but the series falls between two stools; the chapters are too short for textbook purposes and too long for background reading. In any case the series is prohibitively expensive (at £11 4s. 0d. for just the first volume). Without doubt the set of four volumes will become a valuable source of reference in libraries at research institutes, but it is difficult to believe that it will find its way on to the bookshelves of more than a few individual students or young cancer workers.

D. T. HUGHES.

What is Known about Candidosis

Symposium on Candida Infections. Edited by H. I. Winner, M.D., F.C.Path., and Rosalinde Hurley, M.D., M.C.Path. (Pp. 249+xii; illustrated. 35s.) Edinburgh and London: E. & S. Livingstone, 1966.

Following the introduction of drugs with an immunosuppressive action such as the corticosteroids and antibiotics with a wide spectrum of activity, fungi were given opportunities to cause clinical infection previously denied them. *Candida albicans* has been the most successful in taking advantage of the new situation, and it is now responsible for a group of pathological conditions known as "candidosis." This, the editors explain, is preferable to the alternative "candidiadis," used in America, on the grounds of priority, brevity, and euphony, and its wide usage in this and other countries. Even so, infections of any severity are still very unusual, and few clinicians have had much experience of them, or clinical pathologists of the organism itself. There was therefore every justification for bringing together twenty experts in their respective fields to take part in a symposium on *Candida*. This volume is an account of the proceedings.

The papers in Part I deal with the pathological potentialities of *Candida*, its isolation, recognition, and antigenic analysis. In Part II there are papers on the efficiency of chemotherapeutic agents, the allergic manifestations that may occur, the experimental production of infections, and the part played by the organisms in animal disease. Part III, which makes up half the book, gives a series of descriptions, often in considerable detail, of the various forms of infection that may be encountered. This naturally includes very full descriptions of candidosis of the mouth, vagina, and urethra, and the special manifestations of the disease in children. The more unusual manifestations, such as candidal infection of the skin, nails, hair, and external ear, infection of the lungs and invasion of the blood by the organism, are also given their due weight. The book ends with a chapter on treatment.

Taken together, these papers throw a flood of light on the subject, and there can be little that is known to which reference is not made somewhere in its 250 pages. It is lavishly illustrated, there is a bibliography at the end of each chapter, and the index is adequate. All connected with its production are to be congratulated.

RONALD HARE.

Immature Babies and How they Grow up

Children of Very Low Birth Weight. By Alison McDonald. (Pp. 126. 25s.) London: Spastics Society (in association with William Heinemann), 1967.

This book reports the results of a follow-up study of more than a thousand children with a birth weight of 1,800 g. or less, born between 1951 and 1953, originally collected by the Medical Research Council for a study of the relationship of retrolental fibroplasia to oxygen therapy. A very high proportion of the children were traced and 1,066 were available for examination. The survey was undertaken in order to identify more clearly the causes of cerebral palsy. The children were between 6 and 8 years of age and were old enough for a satisfactory neurological and intelligence assessment to be made. They were collected from 14 cities in different parts of Great Britain. Of the children who weighed less than 1,360 g. at birth 33% had a congenital defect, and from this weight up to 1,800 g. 24% had a congenital defect.

The author divides the factors causing low birth weight into two broad groups—those leading to early delivery and those depressing foetal growth (the "small for dates" babies—S.F.D.). Apart from retrolental fibroplasia the greatest hazards following early delivery were spastic diplegia and deafness, while the S.F.D. children tended to suffer from cerebral palsy other than spastic diplegia, from cataracts, fits, and mental retardation. Dr. McDonald concludes that the damage resulting in spastic diplegia and deafness occurred postnatally, particularly in association with cyanotic attacks, and the strong correlation found with gestational age suggested that immaturity was a factor of primary importance.

The S.F.D. children tended to have signs of cerebral disease—presumably consequent upon prenatal brain damage. The author

draws several other important conclusions from a study of these two aetiological groups. She supports the hypothesis that the periventricular lesions described by Banker and Larroche may well prove to be the cause of spastic diplegia. She analyses the statistical evidence concerning cerebral palsy, intelligence, eye defects, deafness, and fits in considerable detail.

In regard to intelligence, Dr. McDonald concludes that when children with severe neurological or sensory defects were excluded the I.Q. did not differ appreciably from that of the general population—the mean was 102.4 (Terman-Merrill revision of the Stanford-Binet test). The lack of correlation between the I.Q. and factors leading to oxygen deprivation around the time of birth suggested that, although cerebral anoxia may lead to death or neurological disorders in small premature babies, it does not affect intelligence.

This is a careful and accurate piece of work which well justifies its selection as the first monograph in a new series of "Research Monographs." Immature babies survive in increasing numbers and we are too ignorant of the aetiological and pathogenetic factors concerned with their abnormalities. Biochemical factors are now being more closely examined, and Dr. McDonald asks for more detailed post-mortem studies by collaborating premature baby units. She hints that the fear of damage by excessive oxygen therapy may have limited its use, with a resulting high incidence of spastic diplegia. There is no suggestion in any of her conclusions that the last word has been written; her work provides a stimulus to further inquiry.

DOUGLAS HUBBLE.

Normal and Abnormal Sexuality

Sexual Problems. Diagnosis and Treatment in Medical Practice. Edited by Charles William Wahl, M.D. (Pp. 300+xxix. 63s.) London: Collier-Macmillan, 1967.

This book originated in a postgraduate course on sexual problems in medical practice held in the University of California. It consists of 22 articles by 18 contributors and is addressed mainly to non-psychiatrists. In the United States, as in this country, the average medical practitioner is insufficiently informed about sexual matters. The book aims at remedying this deficiency.

Although the majority of the contributors are psychoanalytically oriented there is no undue emphasis on theory nor do they recommend psychoanalysis for all cases of sexual disorder. There are articles on taking a sexual history, on physical symptoms that may reveal sexual conflict, on sexual problems in gynaecological practice, on the psychological effects of abortion, on impotence, on promiscuity as a symptom of anxiety, the intersexed patient, and several other subjects. Inevitably, there is much overlapping. The presentation is neither systematic nor comprehensive, but it is lucidly written, and should help to introduce general practitioners and other doctors into the problems of normal and abnormal sexuality.

E. STENGEL.

Significance of the Systolic Murmur

The Innocent Murmur. A Problem in Clinical Practice. Edited by Cesar A. Caceres, M.D., and Lowell W. Perry, M.D. (Pp. 300+xvi; illustrated. 97s. 6d.) London: J. & A. Churchill. 1967.

This monograph, with 23 eminent American cardiologists as contributors, deals with the history of innocent murmurs, mechanism of sound production, and principles of phonocardiography, as well as discussing the aetiology and significance of the systolic murmur.

Much of the text is taken up by a verbatim discussion between cardiologists, and is presented in the form of reports on panel discussions or clinicopathological meetings. This may appeal to some readers, but it takes a long time to sort the wheat from the chaff and at the end one is not always clear about the outcome of many pages of talk. It is unfortunate that the phonocardiograms, so vital to augment the text, are of such a poor quality and are not printed on art paper.

The cardiologist will find profit in reading through the views of his American colleagues on this most important subject. The misinterpretation of innocent systolic murmurs has led to much unwarranted cardiac invalidism in the past, and authors are to be congratulated on bringing together the views of all the leading authorities in this one volume. There is an excellent collection of references.

J. P. SHILLINGFORD.

Hierarchy and Culture

Caste and Race. Comparative Approaches. Edited by Anthony de Reuck and Julie Knight. (Pp. 348+xi. 60s.) London: J. & A. Churchill. 1967.

This is another symposium in the Ciba series for the promotion of understanding and knowledge on an international basis by bringing together persons prominent in their

respective professions for free exchange of views and ideas. A previous contribution *Man and Africa* is an outstanding example and remains on my bookshelf as a significant reference on Africa for a practising public health physician. The present volume follows the same format of a series of carefully prepared papers, each followed by open discussion.

It is not a book for the busy general physician to relax with; it is an intellectual contribution to a current and persisting anachronism to Western civilization's concept of an egalitarian society. Sociologists, however, like anthropologists and historians, follow the event, and by analysing past social experience hope to give the world a greater understanding of the present. The present volume attempts to do this by making a comparative study of social segregation as it occurs around the world, whether it be due to traditionally derived cultural customs or ethnic groupings. Both may be ascribed to an accident of birth; which thus determines man's status in society. Its effect upon modern outlook will depend upon how far its contents can be translated into easily assimilable terms. Those most in need of its understanding analysis are least likely to read it in its present form.

The symposium is in difficulties from its very inception in its attempts to define and distinguish caste, class, and slavery; but this is an excellent opening chapter. Perhaps the most concise and embracing definition of caste occurs some three chapters later: "a caste system occurs where a society is made up of birth ascribed groups which are hierarchically ordered and culturally distinct. The hierarchy entails differential evaluation, rewards, and associations" (page 48). Or, more simple (page 58), "Caste is people, and especially people interacting in characteristic ways and thinking in characteristic ways." Later on a moment of truth? (page 81): "They do not want equality—they want superiority; lower castes want to move up the ladder rather than to eliminate the ladder." Degrees of slavery are observed from chattel slaves with involuntary servility

to bond slaves with voluntary servility. The rights and privileges of slavery are noted (an article in *Life* magazine of 6 October 1967 entitled "Dead Hand of the Ottomans" graphically portrays this). The term "unfreedom" is coined.

Perhaps class is the most difficult to define and the most clearly understood. The haves and the have-nots; the professional status syndrome where profession supplants economics; and the "degenerate culture group view." This latter is described as an essentially practical class concept defined in terms of speech, standards of living, and interests displayed. That is, people tend to group themselves according to the similarity of their ways of living. The common fundamental facets of race and caste discrimination are later defined as "Besides endogamy and status stratification, the concept of pollution in sexual relations, commensality and residence, and belief in the inheritance of biopsychological qualities along racial or ethnic lines, are common properties of the two sets of relationships" (p. 98).

A review of this length cannot do justice to such a symposium. From discussions on definitions, philosophical and comparative sociology, chapters are devoted to discussions of the problems of discrimination on a geographic basis. Much of the tone of the book is set by the realization that the very words race, caste, slavery themselves carry implicit overtones of prejudice. Curiously enough, the word tribalism is neither mentioned nor defined. Africa receives scant attention, though there is brief mention on pages 109 and 110 of East Africa, and again reference is made to the difficulties of assimilation experienced by Francophone negroes in France—the psycho-dynamics of acculturation in relation to Francophone Africa. Perhaps there are lessons for the physician in the phrase "Each social class has a kind of sub-culture of its own within the wider whole." And, maybe, we as physicians would do well to consider our own subculture classes in terms of status hierarchy.

MEDICAL HISTORY

The Worshipful Society of Apothecaries of London—1617–1967

W. S. C. COPEMAN, C.B.E., M.D., F.R.C.P.

[WITH SPECIAL PLATE BETWEEN PAGES 540 AND 541]

Brit. med. J., 1967, 4, 540–541

The Ancient City Companies and Guilds were formed in mediaeval times as "friendly societies" for mutual help among members of certain trades and crafts, and for the relief of their distressed colleagues. Since Elizabethan times the Grocers' Company had imported spices and drugs from the newly discovered countries to the far east and west, and had compounded medicines from these. Those members of that company who performed this useful function were known as apothecaries. As early as 1525, however, we hear of the Apothecarial Grocers petitioning for a corporation of their own, as their art was a separate one and should not be subordinated to fallible tradesmen like grocers who favoured only the mercenary part of their trade. Their wish was not then granted, but it became obvious that secession was imminent, as a new profession, pharmacy, involving special training and study, was evolving.

The Charter

In 1616 the Royal Apothecary, Gideon De Laune, with the co-operation of Sir Theodore de Mayerne, the Court Physician, again petitioned King James I for a charter such as had been granted a century previously to the physicians. Lord Chancellor Francis Bacon approved, and the King agreed, saying, "Grocers are but merchants, the business of an apothecary is a Mystery, wherefore I think it fitting that they be a Corporation of themselves." This, however, greatly displeased the powerful city fathers and the College of Physicians, which was then in the city; so in conjunction they placed every obstacle in the path of the new company and succeeded in delaying its charter until 6 December 1617, on which day it finally passed the Great Seal. Thus the apothecaries were free at last, but with little money and no headquarters. They possessed boundless confidence in their future, however, and their written records have survived unbroken from that day, enabling us to reconstruct their unique story.

The new company, or society, now regarded its main function as being to improve the quality of all drugs sold to His Majesty's subjects, and also to supervise and improve the qualifications of the vendors. Their charter gave them the right to search apothecaries' shops within a seven-mile radius of Cornhill, and to destroy all materials found which they considered below standard. With incautious naiveté, which they would regret for two centuries, they agreed "to put their dependence upon the liberal-minded College of Physicians," whose prescriptions they dispensed and who they felt sure would be more sympathetic to their aims than the mercenary grocers.

With the death of their protector King James, however, the College at once claimed before the Privy Council the right to control "those lowly dispensers of drugs and boluses." But the newly incorporated apothecaries had stout hearts and nursed ambitions of their own; they boldly opposed the claims of the College—and won—but not before the physicians had obtained a draft Order in Council which ordained that "No Apothecary was to sell any poyson drugges or medicines" except on their prescription. The indignant apothecaries suggested with some justice that if to prevent danger they might not sell drugs, then cutlers should be forbidden to sell knives and the gun-makers pistols. This argument impressed the Attorney-General, and the matter was dropped.

Evolution of the General Practitioner

London in 1617 was still a mediaeval city in appearance, confined within walls, with dark narrow streets bordered by rickety half-timbered homes in which the merchants lived above their businesses. The chief highway was the river, and the whole was dominated by the towering Gothic pile of St. Paul's. Its chief playwright was William Shakespeare. The apothecaries mostly congregated around "sweet-smelling" Bucklebury, where they stored and retailed their drugs and other medicaments.

At the time the medical profession consisted of physicians, who were learned, unpractical, scarce, and expensive; surgeons, who were unlettered craftsmen of lowly status; and quacks—some very picturesque characters, but undoubtedly dangerous. Until the dissolution of the monasteries the monks had also occupied an important role in the care of the sick poor. There were no general practitioners or family doctors.

It seems inevitable that apothecaries should have often included a little free advice with the package of drugs, and so in time the indigent sick came to look upon the apothecaries as their general medical advisers and attendants. Indeed, this position seems to have been forced upon them both by the large numbers of sufferers "unable or unwilling to fee a physician" who sought their aid, as well as the exodus of most physicians from the city during the frequent epidemics of the plague. They recognized that they had no right to claim a fee for such advice, but found adequate remuneration through their charges for dispensing the remedies. At a later stage, particularly in country districts, the apothecary would leave his shop and visit such clients at their homes, so becoming in fact their general medical attendant.

Such behaviour infringed the College of Physicians' legal monopoly of medical practice within the city and for seven

THE WORSHIPFUL SOCIETY OF APOTHECARIES

W. S. C. Copeman

The Great Hall. This is now the oldest surviving hall in the City of London. The 24-branch candelabrum was presented by Sir Benjamin Rawling, who was Master of the Society in 1736. The great chest was given to the Society in 1668 by Sir William Clarke.

The Entry to the Hall, in Black Friars Lane. This was built in 1786, and opens into a paved court.

The Court Room. This was completely panelled in oak in 1672 and it contains portraits of previous officers of the Society, among them of Gideon De Laune — the reputed founder of the Society—and of John Hunter, by Reynolds.

W. S. C. COPEMAN: THE WORSHIPFUL SOCIETY OF APOTHECARIES

The Parlour. This contains a pine mantel by William Kent, by which a wartime bomb fell but failed to explode.

The Court in Session. Members of Court (from left to right) Mr. Ian M. Jackson, Mr. Ernest Busby (clerk), Sir Ronald Bodley Scott, Dr. R. Donald Teare, Dr. E. Grey-Turner, Dr. G. B. Mitchell-Heggs, Sir Brian Windeyer, Sir Arthur Porritt, Mr. Alistair L. Gunn, Sir John Richardson, Dr. Redvers N. Ironside, Dr. Peter Bishop, The Bedel, Dr. Hugh M. Sinclair (Senior Warden), Dr. Macdonald Critchley, Mr. T. Keith Lyle (foreground), Mr. Harold C. Edwards (Master), Dr. R. R. Trail, Mr. Henry R. Thompson (Junior Warden), Mr. A. M. A. Moore, Sir Charles Dodds, Dr. W. S. C. Copeman, and Sir Cecil Wakeley.

miles around, and was punishable by imprisonment on the orders of its president in any prison other than the Tower of London, and confiscation of their stock. Thus the issue between the College and the company crystallized into the latter's right to practise (without direct fee) as well as dispense.

The dispute continued with increasing acrimony throughout the years of the Civil War, during which the city influence of the apothecaries increased as the College followed the King to Oxford. Both bodies lost their premises during the Great Fire of London, but the apothecaries, being on the spot, were able to rebuild theirs in its present form on the site of the old Black Friars' Monastery. As they increased in status and wealth they added to their possessions a State barge with 18 lusty watermen, and in 1673, as London expanded and it became more difficult to find the wild herbs and roots which were their stock-in-trade, they acquired a physic garden of four and a half acres on the river bank at Chelsea from Lord Cheyne, where these could be grown and the instruction of their apprentices carried out. In the early eighteenth century the company's finances declined, and but for the generosity of Sir Hans Sloane the garden would have had to be sold. Many of those whose names feature on the roll of fame for botany and medicine received their training in this garden, which still stands where it did and is a focal point of modern botanical and agricultural research under the auspices of London University.

The Rose Case

In 1704 the final clash between the College and the apothecaries took place. William Rose, a liveryman of the company, was sued as a test case by the College for treating a patient without the intermediary of a physician, and the case was decided against him in the Queen's Bench Division. The House of Lords, however, reversed this decision on appeal, holding that despite the existing law it was contrary to custom and against the public interest to prevent the giving of advice and treatment by members of the Apothecaries' Company. Thus the age-long monopoly of the College was broken. Henceforward the apprentice who had satisfied his examiners at Apothecaries' Hall and taken up the Freedom of the City was free to practise, without fear of prosecution, as well as compound his medicines, although he had another century to wait before he was allowed to charge for his advice as well as his remedies. It was in this way that the British dispensing doctor arose, as did the public's continuing expectation of a routine bottle of medicine when they visit their general practitioner. It was not until the Medical Act of 1858, which established the General Medical Council, that the practice of charging a fee for advice or visiting only was finally legalized and the modern family doctor emerged.

Some apothecaries did not aspire to become medical practitioners, however, and such men continued in pharmaceutical business, some of which prospered greatly and grew into firms whose names are today household words. Others broke away and in 1841 formed the Pharmaceutical Society. Still others answered the call of science and followed the academic path.

Reform

Following the political unrest engendered throughout Europe by the French Revolution the desire for "reform" spread rapidly, and the medical fraternity became involved. The chief need was thought to be for the institution of more systematic and practical teaching which would culminate in a standardized examination system. These matters were long debated in Parliament but found little support from the two Royal Colleges.

It was therefore a surprise to the Society of Apothecaries, who had been forward in this field, when the choice fell upon them to carry through these reforms. By the great Apothecaries' Act of 1815 the Society suddenly found itself in control of all general medical practice throughout England and Wales, and in the recent words of Sir Zachary Cope: "There are few in this generation who realize what an important part the Society of Apothecaries has taken in the development of medical education in this country, and in creating that type of modern practice which is a cause for legitimate pride."

The lives of Englishmen have always been ruled more by custom than logic, and the medical profession, as Underwood has pointed out, has developed in a way unlike anywhere else in Europe. For a city mercantile company to have been entrusted by the State with the control of a learned profession, as were the apothecaries by the Act of 1815, might seem inconceivable. The task was, however, willingly undertaken, and, possibly somewhat to their own surprise, brilliantly carried through. Thus the erstwhile apprentices of a city trade-guild rose from the humble status of mere minor shopkeepers and developed in the course of three centuries to that professional status which had always been their ambition, and by the end of the Victorian era they could show clear title to rank as members of a learned and respected profession, as they do today.

Present and Future

The Society maintains the mediaeval domestic hierarchy common to all city companies. The apprentice becomes in due course a yeoman (or journeyman), and later, if approved, a liveryman, and so entitled to the Freedom of the City and all those privileges which accompany such status. The governing body is the Court, which consists of 24 senior members, headed by the master and his two wardens.

A monthly examination is held for candidates for the Society's medical qualifying diploma (L.M.S.S.A.); and postgraduate diplomas are also awarded in midwifery, industrial health, and medical jurisprudence. Its certificate in dispensing is also eagerly sought by hospital and commercial technicians. The study of history is fostered by the Faculty of the History of Medicine and Pharmacy, which like the parent Society has a number of endowed lectureships, including that named after Gideon De Laune, its founder.

The continuing interest of the Society in medical education—a subject in which it pioneered—was recognized by the recent request for two memoranda by the Royal Commission on Medical Education, which is at present sitting.

As to the future, the Society looks forward confident that it will continue to play an important part in the continuing development of all branches of our profession. It is thus perhaps fitting to end this brief epitome of the Society's long and eventful period of evolution with the pious aspiration of its members as expressed in the Master's Toast given after every meal: "The Worshipful Society of Apothecaries of London, May it flourish, root and branch, giving help and health to all—till Time ceases."

The illustrations are taken from the *History of the Worshipful Society of Apothecaries*, by Dr. W. S. C. Copeman, by kind permission of the Pergamon Press. This book was published on 30 November, price 63s.

GENERAL PRACTICE OBSERVED

An Appointment System Service for General Practitioners:
Its Growth and Present Usage

BRUCE CARDEW, L.M.S.S.A.

Brit. med. J., 1967, 4, 542-543

"An appointment system has completely altered our lives; it has brought order out of chaos and we can never cease to wonder how we endured our old ways so long."

This paper provides an analysis of the use to which a particular appointment system service given to N.H.S. general practitioners has been put during the past seven years. The launching of the service was undertaken not with the idea that it would provide subsequent material for research but solely to help general practitioners. Nevertheless, this retrospective approach does provide information which will, I believe, be of interest to those concerned with the changing pattern of general practice in this country.

History

In 1959, when I was editor of the *Medical World*, it was thought desirable by my colleagues that guidance should be offered to general practitioners who wished to introduce an appointment system into their practices. Since little information had been published on the subject, we had to look to the experience gained by individual practitioners who had themselves run appointment systems over a period of years. Seven doctors were approached to form a committee to pool their experience and draft a handbook of advice. It was later agreed to make a short discussion film, "Appointment Systems in General Practice," based on the recommendations in the handbook.* The cost of making the film and printing the handbook was generously borne by Messrs. Lloyd-Hamoll Ltd., who decided also to provide any interested general practitioners with an appointment diary and a continuing supply of sheets. This service is referred to in the article as the A.S. Service.

At first the demand for the A.S. Service was small. It grew gradually until a fresh impetus was given by the introduction of the new method of payment for general practitioners under which a substantial part of the cost of employing receptionists

TABLE I.—Approximate Number of G.P.s Using the A.S. Service at End of Each Year

1961	1962	1963	1964	1965	1966	1967 Oct.
250	700	1,500	2,300	3,200	4,500	7,840

was met by direct repayment. Since the presence of a receptionist is a virtual sine qua non in the introduction of an appointment system the recent increased demand is readily explained. The rate of growth of the A.S. Service is shown in Table I.

Evaluation of the A.S. Service

Late in 1966, when it became clear that a large number of practices were already using the service and that the demand

was likely to increase, I felt that the time had come to reappraise the advice offered in the handbook in the light of the practical experience gained by thousands of doctors who had used the recommended system. A questionnaire was sent to all continuing users asking for suggestions for modification, however minor.

The response rate was 85%, and the forms were sent to the Gallup Poll for analysis. The publication here of the results would not be of general interest, but I can say that 87% expressed positive or tacit approval of the existing system. The suggestions for modification mostly related to the time allowed on the appointment sheets for seeing a patient. Some wanted a longer period, others a shorter one. No group represented more than 1% of the total number questioned. The conclusion which emerged was that the A.S. Service met to a very large extent the requirements of the various types of practice in which it was used. I have no doubt, however, that some doctors, having used the service and having for some reason found that it was unsatisfactory, abandoned it and introduced some variation more to their liking. These doctors would not have received our questionnaire, and their views would not be revealed in our records.

How Many Practices Run An Appointment System?

In Table II are set out the number of doctors in each English county and in Scotland, Wales, and Northern Ireland using the A.S. Service. In the left-hand column is included for comparison the number of N.H.S. general practitioners practising mainly in the area concerned. These numbers are not identical with those shown on local executive council lists, because doctors often practise in several adjacent areas and their names appear on two or more lists. The users of the A.S. Service are divided into those providing a full appointment system to their patients and those providing a partial system. This is clearly an arbitrary distinction and needs explanation. It was decided to call any system "full" where over 80% of surgery consultation periods were available for seeing patients by appointment. Where the percentage was less than 80% doctors were asked to estimate the percentage of patients seen by appointment. An analysis of their replies is set out in Table III. Many expressed their intention of extending the use of the system as soon as circumstances permitted.

Table II also gives the relevant percentage figures of use of the A.S. Service in each county and region.

Discussion

Table I shows that there has been a large increase in the number of appointment systems introduced by N.H.S. general practitioners in recent years. The figures given here relate solely to one particular service and should not be equated with the total use of appointment systems in the country. Unfortunately there are no official sources of information available to complete the picture. Evidently there must be many

* A *Medical World* film distributed by the B.M.A. film library and by Sound Services Ltd.

practices running appointment systems of their own design which are not taken into account in this article.

Using the figures given in Table II as minimum ones and allowing for some hundred additional practices using other systems, one can say with certainty that *a third of all N.H.S. practices are offering a complete appointment system to their patients*. This means, in effect, that at least 17 million patients can now see their family doctors by appointment.

§ Excluding part of Dorset and the Isle of Wight included in Region 9.

The recent striking increase in the introduction of appointment systems (2,000 additional doctors have adopted the A.S. Service during the last nine months) suggests that within a few years the great majority of general practitioners will see all patients by appointment.

The geographical distribution of the use of appointment systems is shown in Table II, and raises questions of interest. Why should Cumberland and Westmorland show a high rate of usage, whereas Cornwall, Devon, and Dorset show a low rate? Why are the figures for London and Middlesex disproportionately low, whereas those for the adjacent counties of Surrey, Essex, and Herts are above the average? At first sight one might assume that factors associated with urban and rural practices could explain the differences, but an analysis of the figures by county does not bear out such an assumption. Fortuitous circumstances may explain some of the differences. If one or more go-ahead practitioners in an area introduce an

* This figure is not the same as that shown in Table II because some doctors did not reply to the question.

appointment system the tendency may well be for others to follow suit. In other areas no such stimulus may be present. One thing is quite certain—appointment systems can be successfully run in the slums of the great towns, in rich residential areas, and in remote country regions.

This article makes no attempt to describe the system recommended by the Appointment System Committee. Neither does it seek to evaluate the benefits of an appointment system to doctors or patients. This task has been undertaken by the Unit of Biometry of Oxford University in their report, *Appointment Systems in General Practice*, recently published by the Nuffield Provincial Hospitals Trust. I commend this report to anyone interested in the organization of general practice. Nevertheless, I must also mention the many hundreds of letters of appreciation sent by users of the A.S. Service. One of the recurring phrases which appear in these letters is reproduced at the head of this article.

My personal view is that an appointment system, after a few months, almost invariably improves the doctor-patient relationship, helps partners to work more closely together, and establishes a framework of orderly practice in which other new developments may take place.

Summary

The problems of appointment systems in general practice were considered by a committee of the *Medical World*, and a system was devised which formed the subject of a handbook.

A service based on the recommendations in the handbook was offered to N.H.S. general practitioners free of charge by Messrs. Lloyd-Hamoll Ltd. The growth of the service and the extent of its present usage are described. Some of the associated problems are discussed.

I wish to thank Drs. J. T. Baldwin (Penicuik), Dr. D. Dean (Birmingham), Dr. A. Elliott (Ilford), Dr. C. K. Elliott (Wisbech), Dr. H. C. Faulkner (London), Dr. H. N. Levitt (London), and Dr. A. S. Playfair (Cambridge), who designed the original handbook on which the appointment system service was based. I believe that the widespread use of the service and the fact that it has not required modification over a period of seven years is clear evidence of the soundness of the advice they offered. The profession owes them a debt of gratitude.

An Appointment System in a Practice with Immigrant Patients

STUART CARNE,* M.B., M.R.C.G.P., D.C.H.

Brit. med. J., 1967, 4, 544-546

In the group practice of which I am a partner patients have been seen by appointment for over six years. We adopted an appointment system when the two previously separate parts of the practice joined on 1 January 1962. It was essential to do something of this nature because of the shortage of space in the waiting-room. The premises now used by the group were those originally occupied by a single-handed general practitioner with a list of 1,600 patients. The space available was barely adequate for his needs. We were able to convert two rooms into extra consulting-rooms, so that at any one time three doctors can now consult, but there was no one room bigger than that used as the waiting-room. Unless we had two waiting-spaces, which would have been difficult to administer, we had no alternative but to restrict the number of patients waiting to be seen at any one time. In that the waiting-room, which has seats for only 12 people, has rarely been full to capacity, and patients no longer have to wait in the street outside; and in spite of there being three doctors, each seeing up to 12 patients an hour; and notwithstanding the fact that some patients (children always) come accompanied by at least one relative, the appointment system has worked.

I have described elsewhere the mechanics of our system of arranging appointments (Carne, 1963). We in our group believe that patients should, whenever possible, have choice of doctor. Even more important, we believe that one doctor should normally treat every member of each family. Most important of all, we aim to arrange our bookings so that each illness episode is dealt with by the same G.P. To assist the receptionists (we need two working full-time on a shift system plus a full-time secretary) we have colour-coded our appointment cards, and we colour-code the family medical record envelopes where one member of the group deals with their personal problems.

A high proportion of the patients in the practice are immigrants (Carne, 1967). Some of the social difficulties, with particular reference to the poverty of their housing, have been described elsewhere (Carne, 1962). It was therefore thought worth while to study the utilization of an appointment system by such patients.

Method

From time to time we have attached to the practice pupils from West London College who are taking the medical secretary's course with the view of obtaining the diploma of the Association of Medical Secretaries. They come in turn for a week of practical experience. For one session during their week the girls from the 1966-7 course were asked to keep a note of the time of arrival, the time of the appointment, and the time the patient actually went into the doctor's consulting-room. One record card was kept for each consultation. As most patients had booked an appointment, and as the medical record envelopes for these patients together with the relevant sheet from the appointment book was available the day before the session, the girls were able to set up most of their study cards in advance. On each card they also put the code number we use for the practice, which enables us to identify the patient's

age, sex, and race.¹ At the end of the study the age, sex, and race groups were sorted by hand. It was then an easy task to determine how early or how late a patient arrived in relation to the time of his appointment (arrival time : appointment time) and how long each patient had to wait (arrival time : time of actual consultation).

Findings

Altogether there were records of 950 patients who had made appointments and were seen. In addition, there were 100 patients who had made appointments and failed to attend. There were also 98 patients who had not made an appointment but wished to see the doctor at the time they visited the surgery. It was (and still is) our practice to offer such patients an appointment either later at that consulting session or at another session. If the patients express a preference to be seen then and there they are invited to wait until there is a gap. If in the opinion of the receptionist they look ill or she thinks it unwise to keep them waiting—for example, some mothers still bring children with a rash to the surgery rather than call for a visit (Carne, 1967)—she will send them through to a doctor ahead of waiting patients who have an appointment. In the rare event of an emergency—for example, a child carried in from a street accident outside—she will even “buzz” one doctor on the intercom and ask him to clear his surgery at once. We rely very heavily on our receptionists for the success of the appointment system.

Arrival and Waiting Times

In Table I are given the waiting and arrival times for all the patients who attended by appointment, and the proportion for the different age, sex, and race groups.

There is hardly any difference in the waiting or arrival time between men and women.

Of all the patients who were seen by appointment 13.8% walked straight through to their doctor on arrival; the doctor was waiting for them. This is because we have always aimed to avoid overbooking. We believe that in general practice there cannot be a predetermined end to an ordinary consulting session. If 85 instead of the usual 75 patients need to be seen (or think they need to be seen) at one session then that session will take that much longer. What is possible is to anticipate difficulties. For example, reappointments are kept to a minimum on Monday mornings; none at all are made for the individual doctor at any session if he wishes to finish early—for example, to go to the theatre. The effect of this is to even out some of the humps of an ordinary practice load, but not all. Because we do this, and because so many appointments are missed, there are gaps into which extra patients can be fitted and there are many times when the doctor has to wait for his

¹ The code used is simple: the last two numbers of the year of birth; 0 and 1 for male and female respectively; and 0-6 to describe the various race groups—for example, 46.1.3 refers to a patient born in 1946, female, and West Indian.

* Excluding 101 patients who did not come into the four groups listed.

next patient. We have discussed this among ourselves. We would rather have these gaps than revert to the pressures of a crowded waiting-room.

There is little difference between the English and Irish patients so far as waiting and arrival times are concerned; the English are a little bit better at arriving promptly. The West Indian patients, however, are not as good timekeepers. A larger proportion come much too early or come late for their appointment. On the other hand, for reasons discussed later, they tend to spend less time in the waiting-room. There were only 24 booked consultations with West African patients recorded for this study, and this number is too small for any valid conclusions to be drawn. If the sample is in any way representative the West Africans are the worst timekeepers of all.

Though there are differences in the waiting times of the patients of varying ages, none of these differences are significant. More children tend to arrive late than adults. The best timekeepers of all are the elderly. Only 20% of the 45-64's come late and only 15% of the over 65's. On the other hand, it should be noted that there are very few immigrants in these two older age groups (Carne, 1967).

The mean waiting time for all the patients is six to eight minutes. As we book two patients every 10 minutes, and are therefore expecting one to wait five minutes, this is about as optimal a degree of efficiency as we can hope for, though we would like to see the extremes reduced so far as is possible.

Fewer of our patients are punctual than the patients described by Bevan and Draper (1967) for the 10 practices they studied. Our practice has had an appointment system five years longer than any of those described in that study. On the other hand, far fewer of our patients wait more than 30 minutes, so that perhaps we have had time to get ourselves better organized. The waiting time is less than that found by Fry *et al.* (1963).

What are the patient's best chances of reducing his waiting time? Table II shows the waiting time in relation to the arrival time, from which it can be seen that the optimal time of arrival appears to be 15 to 24 minutes late; 4.3% of all the patients chose such a time of arrival. It is certain that if the other patients also arrived as late the system would collapse. In

TABLE II.—Time Spent Waiting by Patients in Relation to Time They Arrived Before or After the Scheduled Times of Appointment (Expressed as a Percentage)

Waiting Time	Arrival Time (minutes)							
	Early				Late			
	Over 25	16-25	6-15	0-5	1-4	5-14	15-24	Over 25
Over 25 min	25	8.7	1.2	0.8	0	0	0	0
16-25 " "	25	4.3	14.6	9.0	3.3	4.7	0	0
6-15 " "	37.5	43.5	37.8	40.7	46.7	48.8	28.6	100
1-5 " "	12.5	21.7	39.0	33.3	36.7	32.6	42.9	0
0 " "	0	21.7	7.3	16.3	13.3	14.0	28.9	0

fact 72.2% of the patients arrived early for their appointment, 2.5% coming 25 minutes or more too early. Bevan and Draper (1967) reckon that patients who arrive between five minutes early and four minutes late are punctual. If we extend this licence to our patients then 81.4% came on time or early.

TABLE III.—Patients Seen Without an Appointment (Expressed as Percentages of the Total Consultations Booked and Unbooked)

Total	Sex	Race*	Age Group
98 (9.4%)	Male 47 (8.9%) Female 51 (9.8%)	English 45 (8.6%) Irish 20 (8.1%) West Indian 15 (11.4%) West African 9 (27.3%)	0-4 21 (15.4%) 5-14 5 (3.4%) 15-44 50 (9.4%) 45-64 17 (9.0%) 65+ 5 (5.5%)

* Excluding nine patients who did not come into the four groups listed.

Unkept Appointments

It is interesting that the number of patients who did not keep a booked appointment is almost the same as the number who came to the surgery without an appointment (Tables III and IV), and that by and large the age and race distribution of these two groups is identical. Our senior receptionist is of the opinion that in the main it is the same patients who miss booked appointments who, when they do come, do so without at first booking. The worst offenders are children under school age and "workers" (those aged 15-44). West Indian and West African patients also seem to find it as difficult to keep appointments as they do to arrive on time. Many explanations could be offered for these differences; each explanation might be valid.

TABLE IV.—Patients Who Did Not Keep Their Appointment (Expressed as Percentages of Those Who Booked an Appointment, Whether or Not They Kept Their Appointment)

Total	Sex	Race*	Age Group
100 (9.5%)	Male 42 (8.0%) Female 58 (11.0%)	English 48 (9.1%) Irish 19 (7.7%) West Indian 20 (14.6%) West African 5 (27.3%)	0-4 22 (16.1%) 5-14 3 (3.4%) 15-44 52 (9.5%) 45-64 16 (8.5%) 65+ 7 (7.7%)

* Excluding eight patients who did not come into the four groups listed.

We also asked 240 of our patients whether or not they wanted us to continue to work an appointment system: 84.2% said they wanted us to continue; 7.7% said they would prefer us not to make appointments; 8.1% said they did not mind what we did. These proportions are remarkably similar to those found by my brother in his practice (Carne and Dell, 1965), and by others (Fry *et al.*, 1963; Dean *et al.*, 1965; Stevenson, 1966).

The sample was not selected for age, sex, or race. It was merely a selection of patients living in the area. Those who did not like making appointments to see their doctor have had

five years to change to another practice where patients can wait their turn during fixed surgery hours.

Conclusion

Several studies, already referred to, have shown that it is possible to organize an appointment system within a National Health Service general practice even where the average time for a consultation is only five minutes. In this study we have shown that the system also works well in a practice with a large proportion of immigrant patients.

The West Indian and West African immigrants are not as good timekeepers as the English and Irish patients, but their lack of punctuality is not sufficiently great to upset the smooth running of the surgery sessions.

It is our belief that the ability to see patients by appointment has been a major benefit to both patients and us. In addition to the advantages referred to by other authors (summarized by

Bevan and Draper, 1967) we are of the opinion that the making of an appointment gives "status" to the consultation. It is the aim of a supermarket to encourage "impulse buying." It is debatable whether "impulse consulting" is in the interest of anyone, notwithstanding the patients who find it difficult to tell the doctor all their problems first time.

CONFERENCES AND MEETINGS

Medicine, Science, and Humanity—Annual Meeting of R.C.G.P.

[FROM A SPECIAL CORRESPONDENT]

The Fifteenth Annual General Meeting of the Royal College of General Practitioners was held in London on 18 November. The Chairman of the Council, Dr. H. N. LEVITT, said that in the year in which the College had been granted the Royal Prefix it was for the first time financially solvent. Fifteen years ago it had set out to convince other doctors, especially those in hospital and in the universities, that the general practitioner had a significant role in the future of medicine. Its views were now accepted, and general practice was recognized as a discipline in its own right. The College's next task was to establish a form of education which would raise the quality and realize the potentialities of general practice.

James Mackenzie Lecture

Giving the James Mackenzie lecture, "Lucerna Pedibus Meis," Dr. RONALD GIBSON (Winchester) emphasized two facts. Firstly, today—as in Mackenzie's time—what mattered most was the family unit. Secondly, throughout the ages the medical profession had a responsibility to society, which was becoming increasingly important today as the influence of the Church and authority declined. He asked whether anything was more likely to disturb family relationships and destroy attempts at collective responsibility than paying adolescents as much as their parents might earn. Fortunately most adolescents emerged unscathed and became useful members of society.

Where had society been found wanting? People had not yet accepted that the failings and shortcomings of the adolescent were those of society as a whole. If people were content to perpetuate this second-rate society they were too insecure and too unstable to benefit fully from a Welfare State. The family was the medium on which the Welfare State could grow and adolescents could thrive, and the State should have a supporting and secondary role.

Problems of Today

On 19 November the College held a symposium on "Combined Operations—Medicine, Science, and Humanity." Opening the symposium, Professor Sir EDWARD WAYNE (Glasgow) said that though we had eliminated the infectious diseases we had other problems to face: the care of an ageing population; the implications of such advances as artificial insemination; and the impact of automation. Scientific advances made the ability to deal sympathetically with human beings more important than ever before.

Professor JOHN ANDERSON (London) spoke about the changing relationship between medicine and society. The medical relationship, traditionally based on a personal contract between patient and doctor, was changing. Individual health was linked to community health, and doctors had a duty to the community as well as to their patients. Doctors' basic premises needed rethinking in this context; the demand for medical care was unlimited and they must learn to reorganize their limited resources to meet it. Computers, by helping people to think logically, could help doctors to deal with the psychological and social pressures of society.

Medical education needed new attitudes if it was to produce doctors who remained students of medicine in a rapidly changing field. The domination of the basic science departments in medical schools must give way to the teaching of community care if future doctors were to combine basic clinical skills with ability to communicate with patients and retain flexible attitudes of mind. In King's College Hospital they were trying to establish general-practitioner teaching for medical students, but were hampered by lack of money. They encouraged students who could find a general practitioner willing to take them to spend a fortnight in general practice during their undergraduate course.

Research in General Practice

Professor Sir MAX ROSENHEIM, P.R.C.P. (London), speaking of the importance of research in general practice, said that it was needed not only to stimulate and improve morale but to cultivate the inquiring minds which good medical schools were producing. The Royal College of General Practitioners had played a very large part in encouraging research which was both operational—organization of general practice, functions of group practices and health centres, the work of the general practitioner—and true medical research, exemplified by the work of Pickles in epidemiology. Both kinds of research needed now a combined operation in which hospitals, local authorities, social workers, statisticians, and doctors all took part, in order to get significant results. More research was needed into psychiatric disorders in the community, and he cited the work of general practitioners such as C. A. H. Watts on depression, Max Clyne on school absenteeism, and Anthony Ryle on neurosis in ordinary families as forerunners. Clinical trials of new drugs were also needed in general practice, and they must be controlled by teams which included clinical pharmacologists and sociologists, if their findings were to be valid. Medical schools now acknowledged their responsibilities to the community. Educationally their task was to produce a general-purpose doctor, who after qualification would be vocationally trained for general practice as for other branches of medicine.

Professor WILFRID CARD (Glasgow), speaking on "Clinical Medicine in the Computer Age," said that the Hippocratic method was coming to an end; the private world of the individual doctor would be replaced by the public world of science. We needed a calculus of medicine, for, whereas the concept of disease was a useful fiction, a patient with signs and symptoms was the reality. A computer if fed the right data could make a diagnosis more accurately and

much more quickly than the most experienced specialist, but computers could not replace doctors because they were dependent on them to elicit the data from the patients. No computer could rival a human being in acuity of auditory and visual perception, and its effectiveness was particularly limited in certain specialties—for example, psychiatry. A computer could increase a doctor's reasoning power and his productivity but would not impair the doctor-patient relationship. The family doctor of the future could become a general medical consultant prompted by a hospital computer.

Medical Education

In the discussion Dr. P. S. BYRNE described the changes in medical education in some provincial medical schools as a breath of fresh air from red brick. In Manchester the general-practitioner teaching unit was the meeting-point of undergraduate, vocational, and in-service education. Dr. D. CROMBIE said that the first essential in medicine was to assess undifferentiated situations. Only a doctor could do that, and since the patient's fears, phobias, and past experience had to be taken into account a personal doctor could do it best. The computer was his tool.

Dr. JOHN FRY thought that research in general practice was being done on a shoe-string in an amateur and incoordinated way. It needed time, money, and team work with experts in other fields. This should be supplied by some agency, such as the Royal College of General Practitioners, the Medical Research Council, or academic departments of general practice in universities.

Dr. W. SIDEL, from the Department of Social Medicine in the Massachusetts General Hospital, said that a computer forced doctors to reorganize their thinking. He stressed the importance of gathering the data to feed it with and of knowing what kinds of data are important.

Medical Ethics

The Hon. Sir ROGER ORMROD, a High Court Judge who is also a doctor, spoke on medical ethics. The Western world was changing from the Christian to the humanistic ethic, and our attitudes to abortion, euthanasia, resuscitation of the aged, and transplantation of organs could no longer be determined by Christian dogma. Social and legal considerations played a part—as, for example, when an epileptic patient insisted on driving a motor vehicle: his doctor must choose between his duty as a doctor and as a citizen and could abdicate that duty to nobody. Renal dialysis posed other ethical problems. The number of kidney machines had to be rationed by available resources in money and personnel, and the responsibility of deciding which patients got them had to be borne by doctors alone; it could not be delegated to lay bodies.

Dr. P. W. BOTHWELL (Birmingham) spoke on "Social Responsibility as a Continuing Concept of Medical Care." Humanity would be best served by dealing medically with people before they got ill, but money and medical facilities were so limited that they had to be given to the already sick. Human beings were interdependent, yet each person wanted to survive and each patient to get better at the expense of the community. The development of spare-part surgery could absorb the whole budget of the N.H.S. if it were allowed to. Research was needed into which diseases could be prevented and how, but, since preventive medicine does not attract publicity or votes, it was difficult to persuade Governments to allocate a greater proportion of the Health Service budget to it.

Professor Sir DENIS HILL (London) discussed future trends. The gap between demand and supply of medical facilities would increase as a better-educated and older population expected more from the complex procedures which increasing specialization would bring. A reorganization of the profession was needed. The most important func-

tion of a doctor was to provide continuing and personal care to his patient and it had to be preserved. Undergraduate education, dominated by clinical scientists working within the framework of physical sciences, must give greater prominence to the teaching of the psychological and social sciences. The aims of medicine differed from the aims of science. The way that patients behave and feel was a dimension of medical aetiology, and a doctor must acquire skill in communicating with patients to elicit the facts about illness. An increasing amount of pure research could be done by non-medical scientists.

Medical education should aim to produce a basic doctor. The future general practitioner would be formed by a vocational training course tailored to his needs as a specialist in community medicine, and he would continue his education throughout his career. The divisive effect of the tripartite N.H.S. would diminish and general practitioners would become increasingly associated with hospitals, not as users of general practitioners' beds and pathological services but as part of a hospital-centred community-orientated health service. The family doctor would continue to look after his patient in hospital, though he would entrust the techniques of diagnosis and treatment to specialists. The mutual esteem and collaboration between general practitioner and consultant which existed before the National Health Service would be re-established. There was no place for medical practice in isolation. People were best served by a complex of general and specialist practice and this was already coming about. Automation would increase productivity and computers would help with diagnosis, but the understanding of the personality of the patient, his history and reactions, demanded human qualities, understanding, and tact. Academic departments of psychiatry and general practice were needed in all teaching centres to establish the importance of medicine as the study of man and disease rather than disease in man.

Applied Microbiology : Global Impacts

[FROM A SPECIAL CORRESPONDENT]

Applied microbiology can make an enormous contribution to the welfare and economy of developing nations. To focus attention on this contribution the second Conference on Global Impacts of Applied Microbiology was recently held at Addis Ababa. The main conference themes were the contribution of micro-organisms to the production of food by fermentation not only of sugars but of petroleum products, including methane; economic aspects of the control of tropical disease; international assistance programmes and training in microbiology; and water microbiology.

Regarding methane fermentation the conference concluded that the potential food production from this source was enormous, but that it would not be technically practicable for a decade. Nevertheless, an increase in basic research into these technical difficulties might shorten this period. The production of protein by yeast fermentation of sugar (particularly waste sugar) had, however, very great unrealized capacity at present. In the

Philippines, for example, 1,323,817,000 litres of coconut milk were said annually to be poured into rivers and streams. This occurred when copra and oil were made from coconuts, and the milk was unwanted even though such a quantity contained 25,000 tons of sugar. Moreover, its disposal into rivers and streams created a hygiene problem. In other regions where sugar was produced from cane much waste also occurred. In India, for example, it was calculated that waste sugar could annually produce 1,000,000 tons of yeast of 50% protein content. It was pointed out that the technique of continuous fermentation, in which the substrate was kept at a constant composition, had great potential for increasing the yield and constancy of the product in this field.

Economic Aspects

The economic aspects of microbiology also received attention. Biological surveillance was being established, particularly by the

World Health Organization in developing countries, and was enabling more effective and more economic health schemes to be put into operation. Such biological surveillance entailed, for example, the collection of sera for immunological assessment from persons of representative age groups over a period. Thus it had been shown that only specific age groups were likely to benefit by inoculation against various diseases—hence effort should be focused on these groups and not on the entire population.

The economic impact of many tropical diseases were discussed, particularly onchocerciasis and schistosomiasis, and for most control would, it was considered, cost considerably less than the losses brought about by the disease. The magnitude of the funds available for health control schemes, however, was agreed to bear no relation to the need for such schemes, and hence priorities had to be assigned among those that were feasible. The application of systems analysis and cybernetics in this field was becoming urgent.

Correspondence

Letters to the Editor should not exceed 500 words.

Pseudomonas Infection in Hospital

SIR,—I was glad to read the report by Dr. J. E. Tinne and colleagues (11 November, p. 313) and your leading article (same issue, p. 309) on this very serious problem. Somebody once said that the *Pseudomonas* is the nearest thing to spontaneous generation, and how right that is. The ever-present danger of *Ps. aeruginosa* cross-infection is most typically exemplified by the situation arising in cases of burns. In my experience hardly any burn case with over 30% of body surface affected and staying in hospital long enough will escape colonization or infection by *Ps. aeruginosa*.

I was pleased to see that the authors regard airborne *Pseudomonas* infection as relatively uncommon, as this accords with my findings. In the last six years, performing weekly slit-sampling of the air in the burns unit, only twice did we isolate a *Pseudomonas* from the air. Furthermore, eight plates were exposed for 24 hours round the clock, changing them every few hours, in a small cubicle occupied by a patient heavily infected with *Pseudomonas*. Not a single *Ps. aeruginosa* colony was found. *Pseudomonas* does not jump, it crawls; and it can be found first of all where there is moisture.

This brings me to the role of the drainage and plumbing system—that is, sinks, wash-basins, and traps. Your leading article is perhaps too cautious in saying that the evidence of infection from sinks and drains, etc., is not clearly established. In fact traps and wash-basins undoubtedly are a reservoir and can and do become a source of cross-infection. On a number of occasions patients' raw areas were colonized or infected by strains isolated from the traps of the wash-basins previous to the patient's admission. The strains belonged to rare pyocyanea groups (pyocin, serological, and phage-typing), and in one case the strain was a Rubrum type, which increased the chance of positive identification. A patient became infected with this strain after the ward had been closed, washed, and fumigated two weeks prior to his admission, and a thorough bacteriological check revealed the presence of the strain only in the wash-basin trap. Once the *Pseudomonas* is established in the trap it is extremely difficult to eliminate. Having had to cope with the *Pseudomonas* problem for many years, and having tried everything in the book and a great deal which is not, I am afraid I do not share the authors' faith in any particular type of disinfectant. After all, most disinfectants in 10% concentration are capable of killing *Pseudomonas* under suitable conditions given sufficient concentration and time, but if the killing time is longer than the drying-out or evaporation time of the disinfectant applied to the surface the whole exercise is pointless.¹

We have compared a number of disinfectants under conditions simulating ward procedures and

the differences in effectiveness of the most commonly used disinfectants, including the one mentioned by the authors, were only marginal. It is not so much the type of disinfectant which matters but the way it is used. There is still not much which can beat thorough cleaning, washing, and removal of plain dirt. It might also be worth while to recall the usual sequence of events leading to prolonged contamination of the drainage system. Perhaps the most common thing falling into a wash-basin is hair, which on reaching the trap curls up and stays there. After some time a hair "cushion" is formed and desquamated epithelium and all sorts of organic debris fill the interstices. *Pseudomonas*, which can grow and multiply at relatively lower temperature, thus enjoys excellent breeding conditions. Being a motile organism it wriggles its way upwards into the basin, finding en route an excellent hiding-place under the strainer, which is inaccessible to cleaning from below and flushing from above and which cannot be sterilized. Strains of *Ps. aeruginosa*, which could have come only from the trap, were frequently isolated from wash-basins. One must also consider the organisms in the numerous crevices on and around the plughole, shed by the contaminated hands of a previous user. Washing under running water does not eliminate the danger of contamination. This was also shown experimentally by seeding the trap and plughole area with a fluorescent dye and *Serratia marcescens*. Both the dye and the organism could be recovered from the hands, obviously due to back-splash. Taking the above into consideration, we have tried to modify the design of the wash-basins. Better access for cleaning, and flushing is provided by having the plughole area sloping and the strainer removable (therefore sterilizable). The overflow has of course been eliminated. Some wash-basins of this modified design were recently installed in the new maternity wing at this hospital.

Further, two potentially dangerous sources of cross-infection, thermometers¹ and flowers, should be mentioned. When contaminated, as is often the case, active dissemination occurs when the thermometer is shaken or the flowers removed and handled. I would like to make another point regarding the common fallacy perpetuated over the years, that *Pseudomonas* is sensitive to drying. In fact, on the floor of the ward, suspended in blood or exudate, as is usually the case, it will survive for 72 hours. Under experimental conditions in a fan-ventilated oven, temperatures of 65° C. for many hours and up to 95° C. for shorter periods of time failed to kill a broth suspension of *Pseudomonas* dried on to lino or a P.V.C. tile.

I am well aware that much of what I have said applies primarily to susceptible patient population at risk, but there are still quite a few misconceptions regarding *Pseudomonas* to which attention needs to be drawn.—I am, etc.,

Queen Mary's Hospital,
Rochampton,
London S.W.15.

J. KOHN.

REFERENCES

- ¹ Kohn, J., in *Research in Burns*, Trans. 2nd Int. Cong., 1966, p. 486-500, edited by A. B. Wallace and A. W. Wilkinson. Edinburgh.

SIR,—We read with great interest the report by Dr. J. E. Tinne and others (11 November, p. 313), regarding an outbreak of *Pseudomonas* sp. cross-infection in a cardiac surgery unit. They mentioned, among other things, the problem of *Pseudomonas* sp. contaminating the ventilator, in particular the humidifier.

At this hospital we found occasionally that the humidifier of the Engström ventilator was contaminated in this way, especially when a patient was treated with the ventilator for a prolonged period. In order to overcome this problem the humidifier is now cleaned and heat-disinfected after each application. It is then filled with a sterile solution of 0.1% chlorhexidine (Hibitane) in water. The necessary refills during actual use are made with sterile water. We checked the results of this method in 57 cases by taking cultures from the humidifier after each usage. In no case did any growth occur.

We disinfect the Engström ventilator by passing ultrasonically nebulized 70% ethyl alcohol through the respirator in a closed system for two hours.

The efficacy of this disinfection is tested by placing filter paper discs impregnated with staphylococci, *E. coli*, and *Pseudomonas* sp. in the circuit of the ventilator before disinfection and culturing from them afterwards. This method has given excellent results and will be the subject of a report in the near future.—We are, etc.,

SIR,—With reference to the recent paper by Dr. J. C. Tinne and others (11 November, p. 313), this is most valuable in emphasizing the importance in apparatus of reservoirs of water that are difficult to drain and easily infected.

In the intensive care of the newborn baby we have come across two unexpected examples of this, which gave rise to potentially dangerous situations. The first was in the water reservoir of the incubators used for premature infants, and the second in apparatus which sucked out the pharynx immediately after birth. Both were exacerbated by faults in the design of the machinery. In the incubators the water could not be drained completely, as the plug was not at the bottom of the tank; the manufacturers have since remedied this defect. Cleaning of the suction apparatus was rendered difficult by the poor quality of the glass of the catch bottles, which it was thus not possible to sterilize by heat, and the presence of what appeared to be an unnecessary number of rubber washers behind which small amounts of moisture accumulate. *Pseudomonas*

aeruginosa has been found repeatedly in these situations.—We are, etc.,

Respiratory Infection in Early Childhood

SIR,—It is encouraging to see that Dr. P. S. Gardner and his colleagues (11 November, p. 316) and your leader-writer (p. 307) are now advocating the use of blood gas and acid-base measurements in the management of the child with severe respiratory infection. However, it is of little use demonstrating the presence of a major degree of respiratory acidosis unless the facilities for treatment are readily available, and this means intermittent positive-pressure ventilation (I.P.P.V.) through a nasotracheal tube. This point does not seem to be emphasized enough in either of these articles.

I would agree that this type of therapy is easily undertaken only in a hospital with facilities for intensive care, but this should not be taken to imply that I.P.P.V. is an extremely difficult technical exercise. A number of centres in Great Britain have this well established as part of a routine service, and it may not be entirely coincidental that two centres reporting series of I.P.P.V. free of major technical troubles have been those where there has been considerable co-operation between paediatricians and paediatric anaesthetists.^{1,2}

The number of children with respiratory infections requiring I.P.P.V. is probably not great, and it is therefore important that experience gained in the operating-theatre in the management of infants with respiratory distress syndrome, apnoeic attacks, or after major surgery, and in older children with status epilepticus, meningitis, tetanus, etc., should be concentrated. This may well mean channelling admissions to larger centres, but it seems unlikely that there will be much progress in further reducing mortality in a number of diseases in children unless this is done.

Surely we have now reached a stage when a children's hospital should find prolonged I.P.P.V. no more unusual or difficult than caring for the more severely ill child with, say, pyloric stenosis or intussusception.—I am, etc.,

Royal Aberdeen Hospital
for Sick Children,
Aberdeen.

Brand Names of Drugs

SIR,—We have read with some concern your editorial attitude (7 October, p. 1) towards the Sainsbury Committee's recommendations that brand names should be abolished for new medicines. In our view too much emphasis has been put on the theoretical advantages of this proposal, while too little weight has been given to the economic and practical considerations.

Firstly, on the economic side, let us assume that a company has developed a useful new product but is required to market it under an

officially approved name. If it were patentable (and often, for a variety of reasons, it is not) the fact that imitators could use the original name would greatly encourage them to obtain a compulsory licence, as they are able to do under section 41 of the Patents Act. Thus the lack of trade-mark protection would swiftly lead to fragmentation of the originator's market, since doctors are unlikely always to specify on their prescriptions the name of the originating company, however great its reputation. The greatly enhanced financial risks involved for the developer would be bound to constitute a severe deterrent to long-term investment in pharmaceutical research in this country. As to export markets, there are many countries where products cannot be sold under brand names unless these have first been registered in the product's country of origin. In any event, the difficulties already explained of establishing a clear lead for the developer's original product in this country would undoubtedly prejudice its export potential.

For the N.H.S., however, the savings from the abolition of brand names would be negligible. There are only a small number of cases where branded products are more expensive than similarly formulated unbranded medicines. It is calculated that savings, if such branded products were eliminated from N.H.S. prescribing, would be something of the order of 0.5% of cost of the pharmaceutical services.

Nor would the abolition of brand names significantly reduce the numbers of differently named preparations on the market. Out of the 2,150 or so branded prescription medicines listed in *Medindex* at the beginning of 1967 there were some 1,780 different formulations each based on different chemical entities. That is, abolishing brand names could reduce the number of differently named preparations only by less than a fifth. Brand duplication is very much the exception, but the fact that it can occur provides for the possibility of competition leading to superior formulations.

In practical terms it is possible that the difficulties of prescribing and dispensing in the absence of brand names have been treated too lightly because there has been too little distinction drawn between the terminology for the chemical *ingredients* and that for the *preparations* which are formulated from one or more such ingredients. For the former, the approved name is unambiguous. For the latter, difficulties would arise from the absence of brand names in at least three ways: firstly, in describing special formulations, such as delayed release capsules, aerosols, or specially flavoured mixtures acceptable to children; secondly, and more particularly, in the case of small but significant variations between such formulations—for example, with capsules designed to release their medicament at different rates; and, thirdly, in identifying specially formulated presentations which were only subtle improvements over the "official" preparations. In theory each could be described in a phrase describing the formulations, coupled with the approved name and that of the manufacturer. In practice this would probably add to the confusion, rather than decrease it. Many of us must have recollections of this type of nomenclature from our time in the Services.

Finally, we do not accept that legislative controls, relying on severe penalties for

improperly formulated medicines, provide the best way of ensuring uniformly high standards of pharmaceutical quality. We believe that the manufacturers' pride in their own products, when marketed under their own brand names, provides a much stronger incentive.

General practitioners are busy men, and the use of brand names can be convenient as well as logical in their prescribing. We believe that the medical profession should give very careful consideration before supporting proposals to abolish brand names for medicines.—I am, etc.,

Pharmaceutical Industry.

London W.1.

Abortion and Conscience

SIR,—Dr. Myre Sim in his letter on abortion and conscience (4 November, p. 297) complains that doctors have no reliable evidence to guide them in their interpretation of the various clauses of the new Abortion Act.

The World Health Organization¹ defines health as follows: "Health is a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity." This definition is surely relevant when one is considering whether or not to advise termination of pregnancy.

Dr. Sim quite rightly feels that the doctor who advises a termination of pregnancy should have a clear conscience that the dangers threatening the pregnant woman are real. Should he not feel that the doctor who advises against termination of pregnancy also has a clear conscience that no dangers threaten the patient? It is ironical that his letter should appear but a few pages after an article (p. 271) describing 48 days' intensive hospital treatment of a woman who died from complications of a self-induced abortion.—I am, etc.,

Aland, Finland.

Institutional Care of the Mentally Subnormal

SIR,—Professor T. McKeown and Dr. I. Leck (2 September, p. 573) have drawn attention yet again to the shortage of facilities generally for the subnormal. These studies have much to commend them, and their accuracy, especially in relation to the needs of adult patients, is not in doubt. However, should their findings be applied to the needs of patients under 16 years of age any future planning based on them can only have disastrous results. Whatever the authors themselves may have intended, their results will certainly be quoted and used by those intent on reducing costs, and therefore some of their omissions should be mentioned. My remarks here refer only to children.

The singular lack of hospital accommodation at the time of their survey for children in Birmingham is mentioned, and it is suggested that this shortage is overcome by it being "a relatively compact area in which

paediatric and psychiatric centres do a considerable amount of investigation which might elsewhere be done in hospitals for the subnormal." Unfortunately, none of these statements is in keeping with the facts. Apart from its "compact" nature not being obvious to me, "centres" in Birmingham have been unable to carry out all the investigations necessary, while in other parts of the country hospitals for the subnormal are generally not equipped to carry them out either.

In the light of the unqualified statement that only seven of the 1,652 patients in hospital were thought to need "medical investigation or treatment of any kind necessitating hospital admission," the expenditure of £2m. on Lea Castle Hospital must appear to be the best blatant outrage to the taxpayer since the cancellation of "Blue Streak." Even more ridiculous, however, is the fact that 560 of its 660 places are already occupied, over 200 by children, more than half of whom come from Birmingham and who were in fact awaiting admission at the time of McKeown and Leck's survey but were obviously overlooked. The number of children awaiting admission to hospitals for the subnormal in Birmingham at the time of McKeown and Leck's survey was I believe over 100, and at present four requests per month for the permanent care of severely handicapped children are received from that half of the city served by this hospital alone.

The establishment of a "multi-disciplinary assessment centre" in this hospital (a report on this is in preparation) and the demand for this indicates the lack of an assessment service for these children in the city of Birmingham in the past. Requests have been received from paediatricians, E.N.T. departments, the school medical service, and general practitioners, so that these children would not appear on the waiting-lists of hospitals for the subnormal. McKeown and Leck's survey could therefore not have encountered this particular group even if it had reviewed the waiting-lists for this or any other hospital for subnormal children. The provision of this service in this hospital has become necessary because previous attempts at assessment had failed at one or other of the existing paediatric, psychiatric, or school clinics. Our experience suggests that Pilkington's 10%¹ is far more realistic than that of McKeown and Leck.

The behaviour of a number of these children is such that the ophthalmological, audiological, and even x-ray studies often require to be carried out in sleep or under general anaesthetic, while adequate psychological assessment can be achieved only by continuous observation over a minimum period of two weeks. Our experience has shown that many of these children cannot be tolerated for more than a few hours in general paediatric wards, and many who have already been returned to schools and training centres had been previously designated "not assessable," "untreatable," or, in desperation, "impossible."

The handicaps for which assistance is most commonly requested are varying degrees of cerebral palsy, deafness, blindness, speech retardation, or combinations of these, often, but not necessarily, associated with behavioural disorders and intellectual retardation. The staff involved in these assessments have been drawn from various specialties—paediatrics, orthopaedics, ophthalmology, otology, biochemistry, psychology, and psychiatry—assisted by specialist teachers, a speech therapist, and a physiotherapist. The waiting-list for such assessments after four months is now over 25, and demand is increasing. None is accepted without one of three consultants deciding that it is impossible elsewhere. Several children are accepted following assessment for varying periods of treatment

or diagnostic teaching, for which special units have been established in the hospital. The majority, however, have so far been returned to the community with recommendations on placement and management.

The service outlined here is far from complete at present, but it would be quite unrealistic to suggest that, even in its present form, it could be carried out adequately on these children anywhere but in the context of a hospital specializing in the treatment and management of the severely handicapped child.

Despite their underestimate of the need, it should be remembered that McKeown and Leck do suggest that the provision of such facilities in hospitals for the subnormal is most desirable. From our brief experience of the demand, this is indeed fast becoming a necessity. Inevitably, however, the cost per patient in such hospitals must rise, and until the controllers of hospital finances are made aware of the need for this progress it can never be achieved. Estimates of the cost per bed in hospitals for the subnormal in the past few years have varied from £10 to £12 per week, whereas provision of the most basic service on the lines suggested above would amount to from £16 to £20 per week. Personal experience, however, has made it apparent that the treasury and finance departments of regional boards have not yet become aware of the necessity for any such increase. The Minister, in his recent directive on "the upgrading of hospitals," indicated his awareness of the need for a rise in standards, but, apart from expressing a pious hope that this might come about, makes no mention of meeting the increased cost. Until hospitals for the subnormal are given the necessary financial support, and until they cease to be looked upon as a "last resort" for the hopeless, neither these advances nor the wishful thinking of the Minister will ever materialize.

Finally, if any justification should be necessary for this expenditure on the handicapped child, it could be mentioned that at least half of these entering hospital at 5 years of age or under can expect to survive for possibly 50 or more years. At a conservative estimate this will cost £30,000 per patient. Surely it cannot require a great deal of foresight to become aware of the advantages of an increase in expenditure, which will then amount to only half the cost in a city general hospital, or one-third that of the teaching-hospital bed, and which could enable 10–15% of these children to be discharged after one or two years, in some cases with no further expense to the hospital service.—I am, etc.,

Lea Castle Hospital,
Wolverley, Worcs.

Ventricular Aneurysm

SIR,—Your leading article (11 November, p. 312) on ventricular aneurysms prompts us to record a physical sign that we have not infrequently observed after extensive cardiac infarction, especially in women. This consists in a lifting or rocking movement of the fourth and sometimes also of the third rib which can be followed by the palpating finger from the costo-chondral junction right out to

the axilla. In a number of cases the movement is visible and we have, in one case, recorded it with a cinecamera. The sign may persist for two or three months, but can also be permanent. Although it more commonly follows anterior wall lesions, we have on at least one occasion observed it after a postero-diaphragmatic infarct.

We can offer no ready explanation for this phenomenon, which has not, to our knowledge, been described before. The fact that it is not due to localized outpouching is clearly shown on radioscopy, when the movement transmitted to the examiner's hand is visible at sites well clear of the left cardiac border.—We are, etc.,

Errors in Blood Transfusion

SIR,—Once again a transfusion catastrophe has received nationwide publicity,¹ and, in so far as it is fatal cases which are reported, we can draw no comfort from the knowledge that the incidence of incompatible transfusion is higher than this annual event would imply. I would suggest that a re-emphasis of certain facts relating to the practice of blood transfusion will not come amiss at this time. Having regard to the complexities of the subject, it might be thought surprising that more difficulty was not encountered, but there is a common theme running through most of these reported accidents. The incompatibility is in the ABO system and results not from technical incompetence but from clerical error.

I believe that a heavy responsibility rests upon the pathologist in respect of both the technical and clerical aspects of this problem. The problem of safeguarding identification of patients clearly varies from one hospital to another, but I cannot help feeling that more attention should be paid to this aspect of transfusion practice. Many hospitals have devised their own internal system; others have not, or at best have failed to enforce it.

Some years ago, at a meeting of the Association of Clinical Pathologists, I demonstrated a system which we have now operated successfully for many years at the Royal National Throat, Nose, and Ear Hospital. We use a three-part label which follows the colour coding employed by the National Blood Transfusion Service. An example is shown in the Figure. When blood is prepared the first and third part are completed and part three is detached and secured to the blood bottle. If there is no state of emergency requiring the immediate issue of the blood parts one and two are sent out on a report form indicating that the blood is available. Before the blood is issued part two has to be completed and returned to

The label in three parts:—

Part 1	Part 2	Part 3
GROUP A Rh POSITIVE	GROUP A Rh POSITIVE	GROUP A Rh POSITIVE
Name _____	Please supply X matched blood for Name _____	X matched with serum of Name _____
No. _____	No. _____	No. _____
Signature _____	Signature _____	Date _____
Attach to Form.	Return to Laboratory	Attach to bottle

the laboratory, where it is checked against part three by the person removing the blood from the blood bank refrigerator. Even if the person is colour-blind they can presumably read, and we lay great emphasis on the proper use of hospital numbers. Both medical and nursing staff receive repeated indoctrination, and all house-surgeons are interviewed at the commencement of their appointment. The system is not foolproof, especially as we suffer in part from the disadvantages of dispersal. However, it does induce a greater awareness of the dangers inherent in the commodity which we are handling, and I would be glad to supply further details to anyone who might be interested.

I am convinced that some system can be evolved to meet the requirements of any hospital, but it must be rigorously enforced. The price of safety is eternal vigilance.—I am, etc.,

Institute of Laryngology and Otolaryngology,
London W.C.1. D. A. OSBORN.

Alcoholism

SIR,—I would like to reassure Dr. J. J. MacSorley (25 November, p. 487) that the National Council on Alcoholism is not solely concerned with the alcoholic addict.

The National Council's activities at the moment are directed towards the discovery of the alcoholic who refuses, through sheer fear of social censure, to consult a doctor or a religious counsellor. For centuries past alcoholism has been mankind's best hidden secret. The more alcoholics the information centres discover the more we shall be able to present to the public known scientific facts about this disease, and this will form part of wider prophylactic measures to deal with it.

Since the aetiological factors of this disease are unknown and no one form of treatment is applicable to all alcoholics, the National Council on Alcoholism entirely endorses the view that prevention is better than cure, and therefore the education of the public, indeed of our own medical colleagues, is of paramount importance.—I am, etc.,

E. LINCOLN WILLIAMS,
President,
National Council on Alcoholism.
London W.C.2.

SIR,—In the article "Clients of Alcoholism Information Centres" (11 November, p. 346) Dr. Griffith Edwards and others show that the clients of the centres differ from those alcoholics on "Skid Row."

A survey of alcoholics admitted to the Addiction Unit of this hospital confirms the findings that "Skid Row" alcoholics do not reach treatment facilities. During the period 1965-6 at the time of admission 66% of the alcoholics were living with their next of kin (wife or blood relation). A one-in-three sample of general psychiatric patients in the same hospital at the same time revealed that only 53% were living with their next of kin when admitted.

The difference between the two groups is not statistically significant, but it is of interest to note that the alcoholics admitted for treat-

ment have been those who are in the main still in close contact with their families.—I am, etc.,

Addiction Unit,
Moston Hospital,
Chester.

R. P. SWINSON.

Bottle Cuts

SIR,—Dr. M. J. McArthur is to be congratulated on his letter (21 October, p. 171) urging the introduction of polyethylene containers to take the place of glass milk bottles. I would go further and suggest banning the use of glass bottles for the supply of milk altogether. The annual toll of casualties from glass used for domestic purposes is truly lamentable and could be largely prevented. Personal suffering and loss of working hours, not to mention the permanent disabilities that may ensue, create a problem of grave concern to all. . . . The campaign for cleaner milk, with its spectacular benefits to health, was waged successfully some years ago despite opposition from certain quarters, so why not a campaign for safer containers.—I am, etc.,

Llanhamlach,
Brecon.

E. F. ADAMS.

Paraquat Poisoning

SIR,—In your correspondence column Dr. K. A. Mourin (25 November, p. 486) has referred to the report of a case of suicide in Israel by subcutaneous injection of paraquat from Dr. Ch. Almog and Dr. E. Tal (16 September, p. 721), in which the transient occurrence of a right facial paresis was observed between the second and fifth days, and has reported a case of his own in which a right lower motor neurone facial palsy developed four days after a febrile episode with sore throat and general malaise, and 10 days after a trivial exposure to paraquat, occasioned by smoking a cigarette rolled with unwashed hands.

There is no doubt that, as Dr. Mourin indeed suggests, the association with paraquat in his case is coincidental. The paresis in the Israeli case was accompanied by signs of pyramidal tract involvement (also transient), loss of abdominal reflexes, and the presence of Oppenheim's sign—conceivably due to temporary vascular disturbances or other local toxic effect following the systemic absorption of a fatal dose. Dr. Mourin's case was clearly a peripheral lesion of the facial nerve (Bell's paralysis), with the fairly common history of a preceding nasopharyngeal infection. Indeed, the description of vesicles on the right fauces suggests the possibility of a geniculate herpes zoster infection. The initial neurological symptoms observed in animal experiments with paraquat,¹ referred to by Drs. Almog and Tal, were seen only in a proportion of animals after single lethal intraperitoneal doses (30-75 mg. ion/kg.), and consisted of hyperexcitability, violent forced movements, and stiffness and incoordination of gait. In no species have lesions of peripheral nerve been produced.

The burning sensation of the tongue in Dr. Mourin's case can, however, certainly be attributed to exposure to paraquat, since it has a pronounced irritant action on mucous membranes, which is the main reason for insisting that concentrated solutions should be handled with care. In spite of extensive

field experience over the past six years, in which by now several million people must have used paraquat more than once, there have been less than half a dozen cases to suggest skin reactions in abnormally sensitive individuals, and none in which any evidence of an allergic state has been demonstrated.

One can only wish that all cases of illness thought to be associated with the use of agricultural chemicals were as fully investigated and clearly reported as Dr. Mourin's.—I am, etc.,

Salmonella in Tortoises and Terrapins

SIR,—Dr. L. T. Newman (4 November, p. 296) was no doubt right to draw attention in his letter to the possibility of human salmonella infection arising from contact with infected tortoises. Terrapins are also imported into this country in large numbers and present a potentially greater hazard because they are aquatic.

A family of two adults and two children were recently under investigation for an infective illness, with symptoms including fever and mild diarrhoea. They had acquired a small Spanish terrapin (*Clemmys leprosa*), which was not healthy from the outset and died soon after the two children fell ill. Cultures from the gut of the terrapin yielded *Salmonella poona*. Although no salmonella was isolated from any member of the family and the two children were shown to have an adenovirus type 7 infection, nevertheless the serum of the elder child agglutinated an H suspension of *Salm. poona* to a titre of 1/40. This suggests that she may have passed through an inapparent infection. Further inquiry showed that the infected terrapin came from a batch of 5,000 imported from Tunisia. Very few of these still remained on the wholesaler's premises, but the water from the tank in which they had lived yielded *Salm. montevideo* and *Salm. anderssoni*.

American reports show that terrapins and their relatives are often infected by salmonellas, including serotypes which are regularly associated with human infection.¹ The water in which infected terrapins are kept is liable to contain salmonellas for long periods, in spite of frequent changes of water.² Terrapin owners are much more likely to acquire infection by repeated exposure to infected water than are the owners of tortoises, which are terrestrial in habit and likely in the main to contaminate only the garden.

It may not be out of place also to deplore the importation of large numbers of these small creatures, which are beautiful when seen in their natural setting but are doomed to die when imprisoned as pets in tanks. The large numbers exported annually could lead to their elimination from the countries of origin.—We are, etc.,

Cancer Hazards

SIR,—Dr. Georgiana M. Bonser (21 October, p. 129) restates the interesting association between the teratogenic and carcinogenic action of trypan blue. In fact observations which could account for the teratogenic action of the trypan blue group of compounds (acid bisazo dyes) have recently been made,¹ and it is interesting to speculate whether the same cellular disturbances might not also be related to some aspects of the oncogenic process.

In rats trypan blue and related compounds are actively phagocytosed by macrophages and by certain extra-embryonic membranes, subsequently entering the vacuolar apparatus of the cells. They accumulate in heterolysosomes, and in this situation actively inhibit the hydrolytic enzymes found in these organelles. In the context of placental function the short-term effect would appear to be an inhibition of embryotrophic nutrition leading to congenital malformation. Investigations to see whether lysosomal enzyme inhibition is in itself associated with carcinogenesis and whether such a cellular event could account for the development of reticuloses are currently under way.—We are, etc.,

M.A.O. Inhibitor Headache

SIR,—To obtain an accurate picture of the pattern of monoamine oxidase inhibitor drug headache, closer observation appears necessary to clarify the picture than is usually possible in general practice. Dr. C. A. H. Watts (28 October, p. 238) reports in his first case that he "took her blood pressure several times." He does not report over what time interval he made his readings.

In 1964 I was treating a depressed patient with Actomol (mefenazine) 5 mg. t.d.s. Six weeks after commencing treatment, instead of her daily English Cheddar-cheese sandwich, she had a sandwich of Canadian "Cheddar." At 11.30 p.m. a pounding headache mimicking a subarachnoid haemorrhage started. I saw her at midnight in very great distress but without neck rigidity. Her blood pressure was then 160/95. In view of the degree of her distress and my anxiety not to give her an unsuitable drug and thus complicate the issue further I admitted her to a general-practitioner bed, and hourly readings showed her blood pressure to be 200/104 at 1 a.m., but by 2 a.m. it was 120/98, never rising higher again, and being 110/82 by 6 a.m.
